

# REVISED STATIC MODELS OF THE THERMOSPHERE AND EXOSPHERE WITH EMPIRICAL TEMPERATURE PROFILES

L. G. Jacchia

## 1. INTRODUCTION

Only last year we published a set of static diffusion models with constant boundary conditions at 90 km and analytically defined temperature profiles (Jacchia, 1970a; hereafter referred to as J70). An effort had been made to increase the ratio  $n(O)/n(O_2)$  above the value of 1.0 at 120 km adopted in previous models [Nicolet, 1961, 1963; CIRA, 1965; Jacchia, 1965a (hereafter referred to as J65)] to bring it in the direction indicated by mass-spectrometer (von Zahn, 1967) and EUV-absorption data (Hall, Chagnon, and Hinteregger, 1967). As soon as the new models appeared, in May 1970, new observational evidence was presented to the effect that the step toward a larger  $n(O)/n(O_2)$  ratio had not been large enough. In a critical survey of all available density and composition data, von Zahn (1970) found that at 150 km the best value of  $n(O_2)$  was only 0.64 that in J70, while  $n(O)$  was larger by a factor 1.37; his proposed total density at 150 km was smaller by 7%. Von Zahn's proposed number densities, total densities, and mean molecular mass are compared below with the CIRA 1965 models, the J70 models, and the present models, in which we have striven, with considerable success, to approach von Zahn's parameters. We have not included a comparison with our J65 models, because their boundary conditions at 120 km were identical with those of CIRA 1965, so that the difference in composition between these two sets of models is minimal at 150 km. In the following, the average number densities are measured in  $\text{cm}^{-3}$ , the total mass density in  $\text{g cm}^{-3}$ , and the mean molecular mass  $\bar{M}$  in  $\text{g mole}^{-1}$  at 150 km:

\* Approximate average temperature for the interval 1961 to 1969 in the system of the models.

In Table 4 of his 1970 paper, von Zahn listed the number densities of  $N_2$ ,  $O_2$ , and O, reduced to a height of 150 km, that were obtained in 44 experiments, both mass-spectrometric and EUV-absorption, from 1961 to 1969. While there is a large discrepancy among the mass-spectrometer data on  $n(O)$ , the same type of measurements show rather consistent values of  $n(O_2)$  – all of them except one smaller than the corresponding value in J70; a similar result was obtained more recently by Reid and Withbroe (1970) from the absorption of  $\lambda 1032$  (O VI), which requires an  $O_2$  concentration at 120 km only two-thirds as large as that in J70. According to von Zahn,  $n(N_2)$  at 150 km is also lower, by 16%, with respect to J70, while the total density is lower by only 7%. Clearly, if we have to decrease  $n(N_2)$  and  $n(O_2)$  by substantial amounts while leaving the total density almost unchanged, we have to increase  $n(O)$ . While mass-spectrometer measurements of  $n(O)$  are too unreliable (Schaefer, 1966; von Zahn, 1967), it is significant that EUV-absorption measurements (Hall, Schweizer, and Hinteregger, 1965; Hall *et al.*, 1967) give, when reduced to a height of 150 km, values of  $n(O)$  consistently about 25% higher than in J65. This value is not too different from the atomic-oxygen concentration that von Zahn derives by subtracting the density sum of all other constituents from the total density and assumes to be the best value under the circumstances.

We found that satisfactory models that would match von Zahn's parameters at 150 km and the observed densities from satellite drag at greater

heights could be obtained by maintaining intact the analytical structure of the J70 models and changing only the numerical parameters. The resulting models are given in detail in Table 6 and summarized in Table 7, at the end of this paper. Owing to the increased concentrations of atomic oxygen, the temperatures necessary to yield given densities at given heights in the satellite region are somewhat lower than in J70 — closer, therefore, to the temperatures obtained by the incoherent-scatter method (Carru and Waldteufel, 1969; McClure, 1969). Lower temperatures are also suggested by the absorption of the  $\lambda$  304 (He II) line as measured by B. E. Woodgate (private communication, 1970).

Since the analytical structure of the basic models is, as we said, identical with that of the J70 models, many of the following descriptive pages will be almost a verbatim repetition of the corresponding pages of SAO Special Report No. 313, except for the numerical values reported in the text and for the correction of a few oversights. There are, however, substantial changes in the description of the individual types of atmospheric variations. While overhauling the basic models, we have also tried to reanalyze these variations. In so doing, we have found that for some of them — the geomagnetic effect, the semiannual variation, and the helium variation — the analytical formulation we had used was inadequate and had to be altered, or even drastically changed. In particular, the dissociation of the semiannual variation from temperature variations has cleared up many puzzling results in the helium-hydrogen region and eliminated the necessity of introducing ad hoc variations for these constituents.

## 2. COMPOSITION

We have assumed that the atmosphere is composed only of nitrogen, oxygen, argon, helium, and hydrogen, in a condition of mixing up to 100 km and in diffusion above this height. We have adopted the sea-level composition of the U. S. Standard Atmosphere 1962 (COESA, 1962) such as would obtain after elimination of the minor constituents and of hydrogen (which is introduced in our models at a height of 500 km). There is some evidence that for helium, gravitational separation starts at a lower height than for the other constituents. To eliminate the inconvenience of a separate homopause for helium, we have had recourse to the artifice of increasing the sea-level concentration of helium by an amount such that the atmospheric densities at heights where helium appears as a major constituent are in agreement with the observed densities. This results in an erroneous helium density below 100 km — a situation we are willing to tolerate in view of the entirely negligible contribution of helium to the total density at those heights. Thus, the assumed sea-level composition is as follows:

	Fraction by volume $q_0(i)$	Molecular weight $M_i$
Nitrogen ( $N_2$ )	0. 78110	28. 0134
Oxygen ( $O_2$ )	0. 20955	31. 9988
Argon (Ar)	0. 0093432	39. 948
Helium (He)	<u>0. 0000061471</u>	4. 0026
Sum	1. 00000	

The resulting sea-level mean molecular mass is  $\overline{M}_0 = 28.960$ .

We have assumed that any change in the mean molecular mass  $\overline{M}$  in the mixing region below 100 km is caused only by oxygen dissociation. Therefore, the amount of atomic oxygen present in the atmosphere is uniquely determined by  $\overline{M}$ . From 90 to 100 km we have used an empirical  $\overline{M}$  profile that had to satisfy certain conditions. Starting from a value not too different from  $\overline{M}_0$  at 90 km, we end at 100 km with a value that in diffusion must yield at 150 km the ratio  $n(O)/n(O_2)$  of about 9.2 obtained by von Zahn for an exospheric temperature of 900° to 1000°K; the temperature profile from 90 to 150 km is adjusted to give the required total density at 150 km. The  $\overline{M}$  profile must end at the homopause with a gradient roughly equal to that given by diffusion conditions immediately above, so that there will be no sharp discontinuity in the  $\overline{M}$  profile across the homopause (in the belief that "natura non facit saltus").

The adopted  $\overline{M}$  profile can be found in the tables. For computer purposes, we have used a sixth-degree polynomial of the form

$$\overline{M}(z) = \sum_{n=0}^6 c_n (z - 90)^n \quad (90 < z < 100; z \text{ in km}) \quad (1)$$

to represent it. The coefficients  $c_n$  are given below:

$$\begin{aligned} c_0 &= 28.82678 \\ c_1 &= -7.40066 \times 10^{-2} \\ c_2 &= -1.19407 \times 10^{-2} \\ c_3 &= +4.51103 \times 10^{-4} \\ c_4 &= -8.21895 \times 10^{-6} \\ c_5 &= +1.07561 \times 10^{-5} \\ c_6 &= -6.97444 \times 10^{-7} \end{aligned} .$$

The number densities of the individual species  $i$  in the region from 90 to 100 km are obtained as follows. From the density  $\rho$ , the total number of particles  $N$  per unit volume is computed by

$$N = A \rho / \bar{M} , \quad (2)$$

where  $A$  is Avogadro's number.

For  $N_2$ , Ar, and He, we have

$$n(i) = q_0(i) \frac{\bar{M}}{\bar{M}_0} N , \quad (3)$$

and for O and  $O_2$ , respectively,

$$\begin{aligned} n(O) &= 2N \left( 1 - \frac{\bar{M}}{\bar{M}_0} \right) \\ n(O_2) &= N \left\{ \frac{\bar{M}}{\bar{M}_0} \left[ 1 + q_0(O_2) \right] - 1 \right\} . \end{aligned} \quad (4)$$

For  $\rho$  in  $g \text{ cm}^{-3}$ , we have used  $A = 6.02257 \times 10^{23}$ .

### 3. COMPUTATION OF DENSITIES AND BOUNDARY CONDITIONS

From 90 to 100 km, for a given temperature profile  $T(z)$ , the density  $\rho$  was computed by integrating the barometric equation

$$d\ln\rho = d\ln\left(\frac{\bar{M}}{T}\right) - \frac{\bar{M}g}{R^* T} dz , \quad (5)$$

where  $g$  is the acceleration due to gravity, and  $R^* = 8.31432$  joules  $(^\circ K)^{-1}$  mole $^{-1}$ , the universal gas constant.

At the height  $z = 90$  km, we have assumed the following boundary conditions:

$$\rho_0 = 3.46 \times 10^{-9} \text{ g cm}^{-3} ,$$

$$T_0 = 183^\circ K .$$

Above 100 km, the number density of each individual species  $n(i)$  was computed by integrating the diffusion equation

$$\frac{dn(i)}{n(i)} = - \frac{M_i g}{R^* T} dz - \frac{dT}{T} (1 + \alpha_i) , \quad (6)$$

where  $\alpha_i$  is the thermal diffusion coefficient. Following Nicolet (1961), we have used  $\alpha = -0.38$  for helium, and  $\alpha = 0$  for the other constituents.

For hydrogen, we have followed Kockarts and Nicolet (1962, 1963) and fitted the equation

$$\log_{10} n(H)_{500} = 73.13 - 39.40 \log_{10} T_{500} + 5.5 (\log_{10} T_{500})^2 \quad (7)$$

to their concentrations at 500 km. We have assumed hydrogen to be in diffusion equilibrium above 500 km; no hydrogen densities are given in the tables below this height.

The acceleration due to gravity was computed from the formula

$$g = 980.665 (1 + z/R_e)^{-2} \text{ cm sec}^{-2}, \quad (8)$$

with  $R_e = 6.356766 \times 10^8$  cm. This equation (Harrison, 1951; Minzner and Ripley, 1956) is an excellent approximation to the actual value of  $g$  (centrifugal force included) for the latitude of  $45^\circ 32' 40''$ .

#### 4. TEMPERATURE PROFILES

All temperature profiles start from a constant value  $T_0 = 183^\circ\text{K}$  at the height  $z_0 = 90 \text{ km}$ , with a gradient  $G_0 = (dT/dz)_{z=z_0} = 0$ , rise to an inflection point at a fixed height  $z_x = 125 \text{ km}$ , and become asymptotic to a temperature  $T_\infty$  (often referred to as the "exospheric" temperature). Both the temperature  $T_x$  and the temperature gradient  $G_x = (dT/dz)_{z=z_x}$  at the inflection point are functions of  $T_\infty$ ; for simplicity, we have made  $G_x$  a function of  $T_x$ .

The quantity  $T_x$  is defined by the equation

$$T_x = a + bT_\infty + c \exp(\bar{k} T_\infty) , \quad (z_x = 125 \text{ km}) , \quad (9)$$

with the constraint that  $T_x = T_0$  when  $T_\infty = T_0$  (i. e., for the hypothetical case in which the exospheric temperature is the same as the temperature at 90 km, namely  $183^\circ$ , there is no variation of temperature with height). The numerical values of the coefficients are as follows:

$$\begin{aligned} a &= 371.6678 , \\ b &= +0.0518806 , \\ c &= -294.3505 , \\ \bar{k} &= -0.00216222 . \end{aligned}$$

For  $z_0 < z < z_x$  the temperature profiles are defined by a fourth-degree polynomial:

$$T = T_x + \sum_{n=1}^4 c_n (z - z_x)^n . \quad (10)$$

The coefficients  $c_1$ ,  $c_2$ ,  $c_3$ , and  $c_4$  are determined by the following conditions:

$$\text{when } z = z_0 \left\{ \begin{array}{l} T = T_0 \\ G_0 = \left( \frac{dT}{dz} \right)_{z=z_0} = 0 \end{array} ; \right.$$

$$\text{when } z = z_x \left\{ \begin{array}{l} G_x = \left( \frac{dT}{dz} \right)_{z=z_x} = 1.90 \frac{T_x - T_0}{z_x - z_0} \\ \left( \frac{d^2T}{dz^2} \right)_{z=z_x} = 0 \end{array} . \right.$$
(11)

These coefficients must be computed separately for every temperature profile, so their tabulation would be wasteful. The equation for  $G_x$  is justified in the following manner. The condition for having no inflections in the temperature profile in the interval  $z_0 < z < z_x$  is given by

$$\frac{4}{3} < \frac{z_x - z_0}{T_x - T_0} G_x < 2 . \quad (12)$$

Experiments with gradients within this range have shown that it is quite feasible to keep the quantity  $(z_x - z_0) G_x / (T_x - T_0)$  constant for all temperature profiles; the best value was found to be 1.90.

For  $z > z_x$ , the temperature profiles are determined by equations of the type

$$T = T_x + A \tan^{-1} \left\{ \frac{G_x}{A} (z - z_x) [1 + B(z - z_x)^\beta] \right\} , \quad (13)$$

where

$$A = \frac{2}{\pi} (T_\infty - T_x) ; \quad B = 4.5 \times 10^{-6} \quad (z \text{ in km}) ; \quad \beta = 2.5 .$$

As can be seen, continuity is provided in both  $dT/dz$  and  $d^2T/dz^2$  when  $z$  crosses  $z_x$ . The inverse tangent was selected among several suitable asymptotic functions because of its ready availability in tabulated form and in computer libraries. The presence of the corrective term  $[1 + B(z - z_x)^\beta]$  frees the temperature profiles from strict dependence on the selected type of asymptotic function.

The following shows the dependence of the maximum temperature gradient  $G_x$  on the exospheric temperature  $T_\infty$ :

$T_\infty$ (°K)	$G_x$ (deg km <sup>-1</sup> )	$T_\infty$ (°K)	$G_x$ (deg km <sup>-1</sup> )
500	6.23	1400	13.41
600	7.57	1600	14.24
800	9.66	1800	14.98
1000	11.22	2000	15.66
1200	12.43		

The family of temperature profiles originated by equations (9) to (14) is graphically illustrated in Figure 1. Figure 2 shows the composition of the atmosphere above 200 km for three representative exospheric temperatures — 600°, 1000°, and 1800°K. Figure 3 shows seven density profiles from 110 to 2000 km for various exospheric temperatures ranging from 500° to 1900°K, and Figure 4 shows how the density  $\rho$  varies with the exospheric temperature  $T_\infty$  at different height levels. Figure 4 is particularly instructive because it shows at a glance how, for heights below 500 km,  $d\rho/dT_\infty$  generally increases with height but decreases with  $T_\infty$ . Above 500 km, hydrogen makes its appearance, causing the curves to have a dip at low temperatures; we thus have a situation in which at a given height a single density value corresponds to two distinct values of  $T_\infty$ .

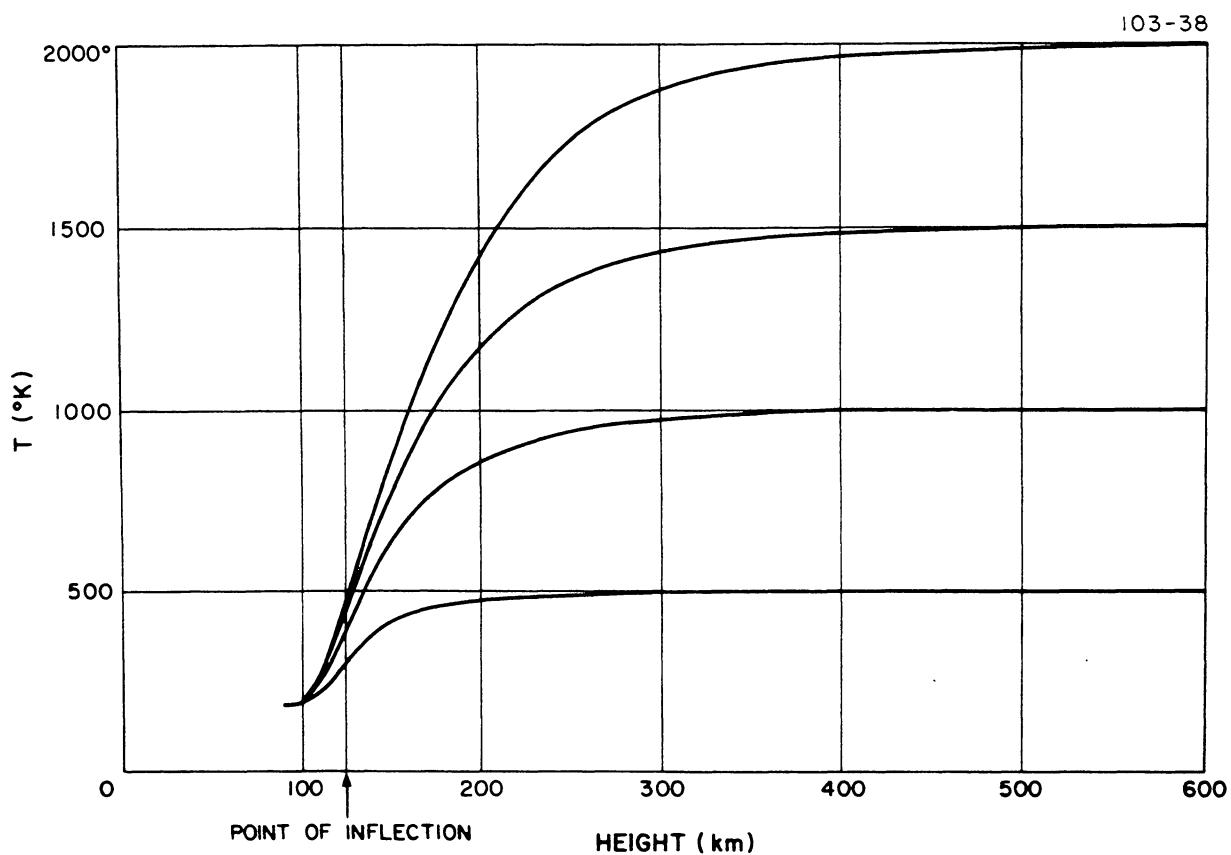

Figure 1. Four temperature profiles from the present models.

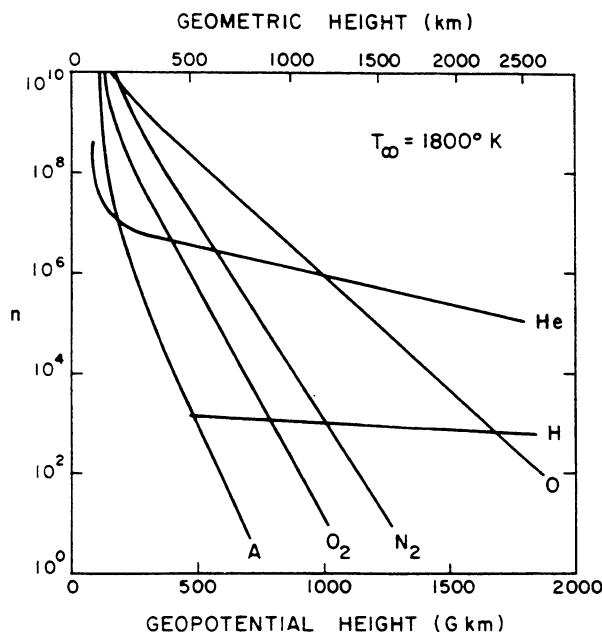

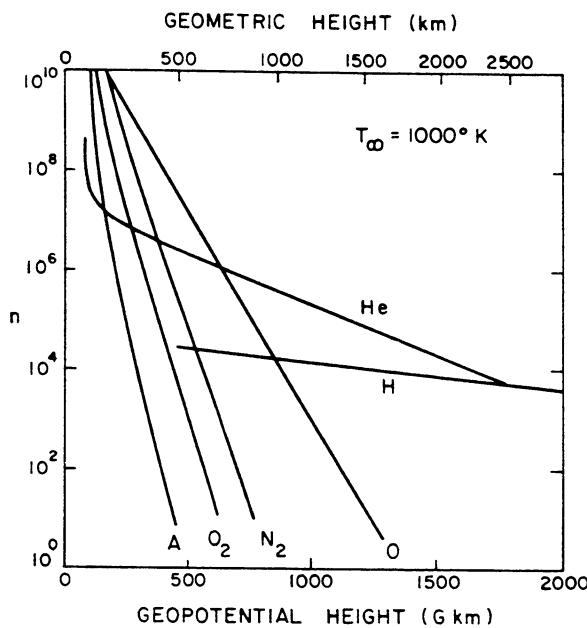

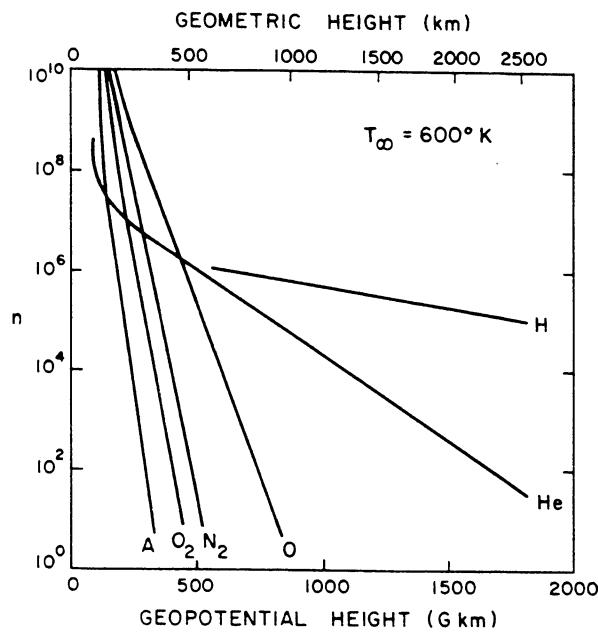

Figure 2. Atmospheric composition for three values of the exospheric temperature. Number densities ( $n$ ) are plotted against geopotential height. The corresponding geometric heights are marked at the top of the diagrams.

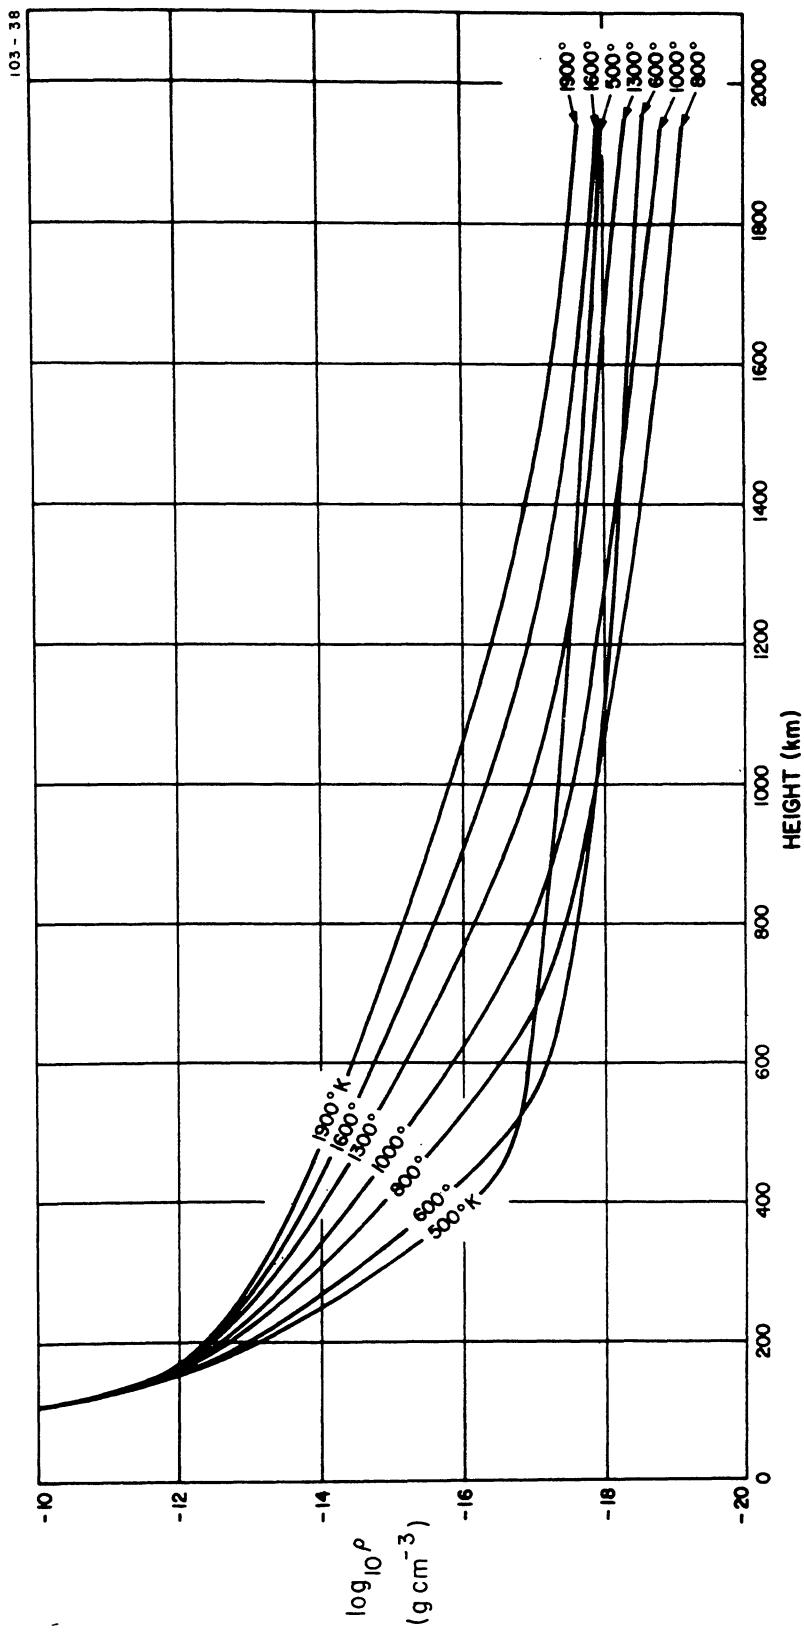

Figure 3. Density profiles for seven values of the exospheric temperature.

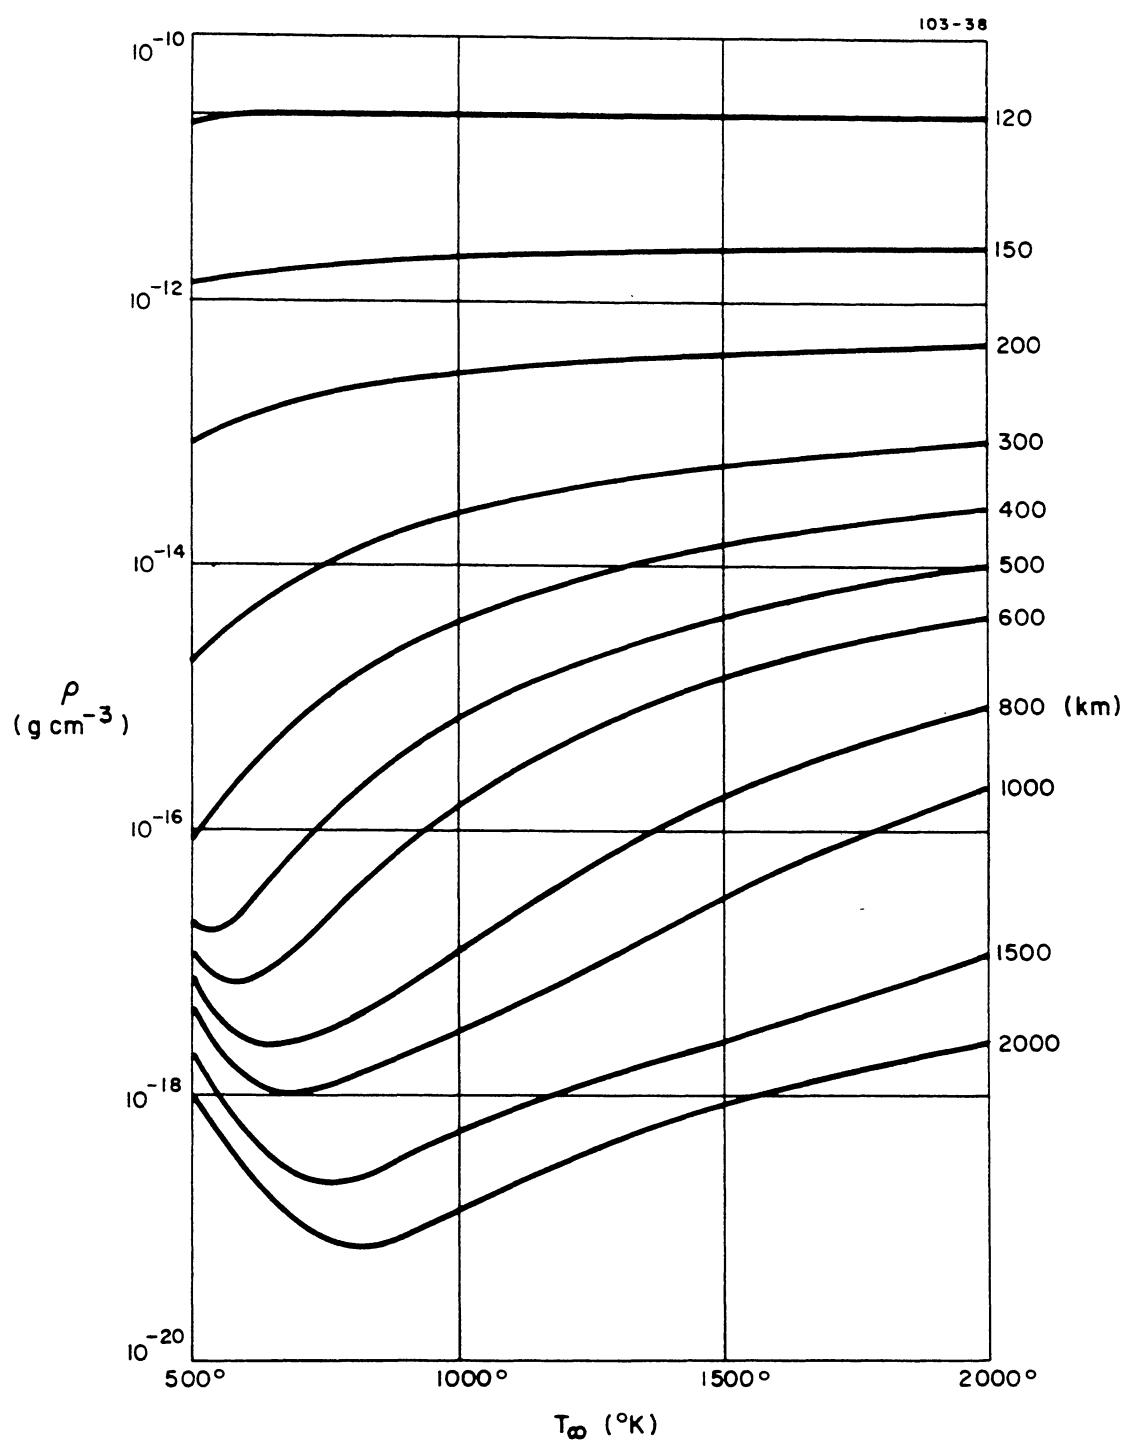

Figure 4. Dependence of atmospheric density on exospheric temperature at different heights.

## 5. VARIATIONS IN THE THERMOSPHERE AND EXOSPHERE

Several types of variation are recognized in the atmospheric regions covered by the present models. They can be classified as follows:

1. Variations with the solar cycle.
2. Variations with the daily change in activity on the solar disk.
3. The diurnal variation.
4. Variations with geomagnetic activity.
5. The semiannual variation.
6. Seasonal-latitudinal variations of the lower thermosphere.
7. Seasonal-latitudinal variations of helium.
8. Rapid density fluctuations probably connected with gravity waves.

All these variations, with the exception of the last type, are subject to some amount of regularity and can be predicted with varying degrees of accuracy on the basis of ground-based observations. It is obvious that static models cannot represent all the different types of variation equally well. They should be quite adequate when the characteristic time of the variation is much longer than the time involved in the conduction, convection, and diffusion processes; when, on the other hand, it is comparable or shorter — as in the diurnal variation and the geomagnetic effect — we must expect poorer results. By this we mean that if we try to represent the observed density variations, we may have to introduce temperature variations that are not entirely correct, or vice versa. Since, by far, the largest observational material consists of density measurements, it is the density variations that we have tried to keep correct. We have no direct evidence so far that the resulting temperature variations might actually be incorrect, although it would not be surprising if they turned out to be so, to a certain degree. Temperatures derived from nitrogen profiles at various times of the day (Spencer, Taeusch, and Carignan, 1966; Taeusch, Niemann, Carignan, Smith, and Ballance, 1968) actually are in relatively close agreement with the J65 static models.

An effort was made in the CIRA 1965 tables to treat the diurnal variation separately; unfortunately, the inadequacy of present-day theory does not justify the tremendous increase in the size of the tables if one were to cover the diurnal variation over the entire globe, instead of restricting it to one particular latitude as in CIRA 1965.

## 6. VARIATIONS WITH SOLAR ACTIVITY

The ultraviolet solar radiation that heats the earth's upper atmosphere actually consists of two components, one related to active regions on the solar disk and the other to the disk itself. The active-region component comes from areas of higher temperature and consists mainly of the spectral lines of highly ionized atoms, such as Fe XIV-XVI, Si IX-X, Mg X; the radiation from the clear disk comes from much less ionized atoms, such as He I-II and O IV, and the helium continuum. The active-region component varies rapidly from day to day in correspondence with the appearance and disappearance of active areas caused by the rotation of the sun and by spot formation; the disk component presumably varies more slowly in the course of the 11-year solar cycle. Since the radiation in the two components is different, we must expect the atmosphere to react in a different manner to each of them — and this is actually observed.

The 10.7-cm solar flux ( $F_{10.7}$ ) is generally used as a readily available index of solar EUV radiation. It also consists of a disk component and of an active-area component, which can be separated by statistical methods by relating the observed values of the flux integrated over the whole solar disk to the corresponding sunspot numbers (Hachenberg, 1965) or, better, to sunspot areas. When the 10.7-cm flux increases, there is an increase in the temperature of the thermosphere and exosphere; for a given increase in the disk component, however, the temperature increases four times as much as for the same increase in the active-area component. Separate values of the two components of the solar flux are not readily available; fortunately, we have found (Jacchia and Slowey, unpublished) that the disk component is, for all practical purposes, linearly related to the flux averaged, or smoothed, over approximately three solar rotations ( $\bar{F}_{10.7}$ ). We can, therefore, replace the relation between temperature and disk component with an equivalent relation between temperature and  $\bar{F}_{10.7}$ .

Since the temperature varies with the hour of the day, with geographic location, and with geomagnetic activity, we must specify the parameters of these variations to which the temperature is to be referred. The temperature  $T_c$  in the equation that follows is to be the nighttime minimum of the global exospheric temperature distribution when the planetary geomagnetic index  $K_p$  is zero. We find that

$$T_c = 379^\circ + 3.24 \bar{F}_{10.7} + 1.3 (F_{10.7} - \bar{F}_{10.7}) \quad (\text{for } K_p = 0) ; \quad (14)$$

$F_{10.7}$  is expressed in units of  $10^{-22} \text{ watt m}^{-2} (\text{cycle/sec})^{-1}$  bandwidth. In this formula, the last numerical coefficient, 1.3, is considerably smaller than the value 1.8 used in all previous models. The change is the result of a new analysis, covering the years 1967 to 1969, which were characterized by a particularly large amplitude of the "27-day" fluctuations. It appears that in deriving the old coefficient (for the J65 models), we did not take the geomagnetic effect sufficiently into account: Most of the large geomagnetic perturbations occur near the maxima of the 27-day oscillations and contribute to increase the amplitude of the density variations.

According to Roemer (1968), the temperature variations occur with a time lag of  $1.0 \pm 0.12$  days with respect to those of the solar flux.

If we want to compute the average exospheric temperature corresponding to a given phase of the solar cycle, i. e., to a given value of  $\bar{F}_{10.7}$ , we must drop the last term of equation (14), which corresponds to the day-to-day variations of solar activity, and add half the diurnal temperature range and the difference in temperature between average and quiet geomagnetic conditions.

Minimum nighttime and daytime maximum exospheric temperatures obtained, with the present models, from drag-derived densities for three long-lived satellites are plotted in Figure 5 against  $\bar{F}_{10.7}$ . To obtain the data points, all variations except the diurnal variation were suppressed. The straight line through the nighttime temperatures is represented by

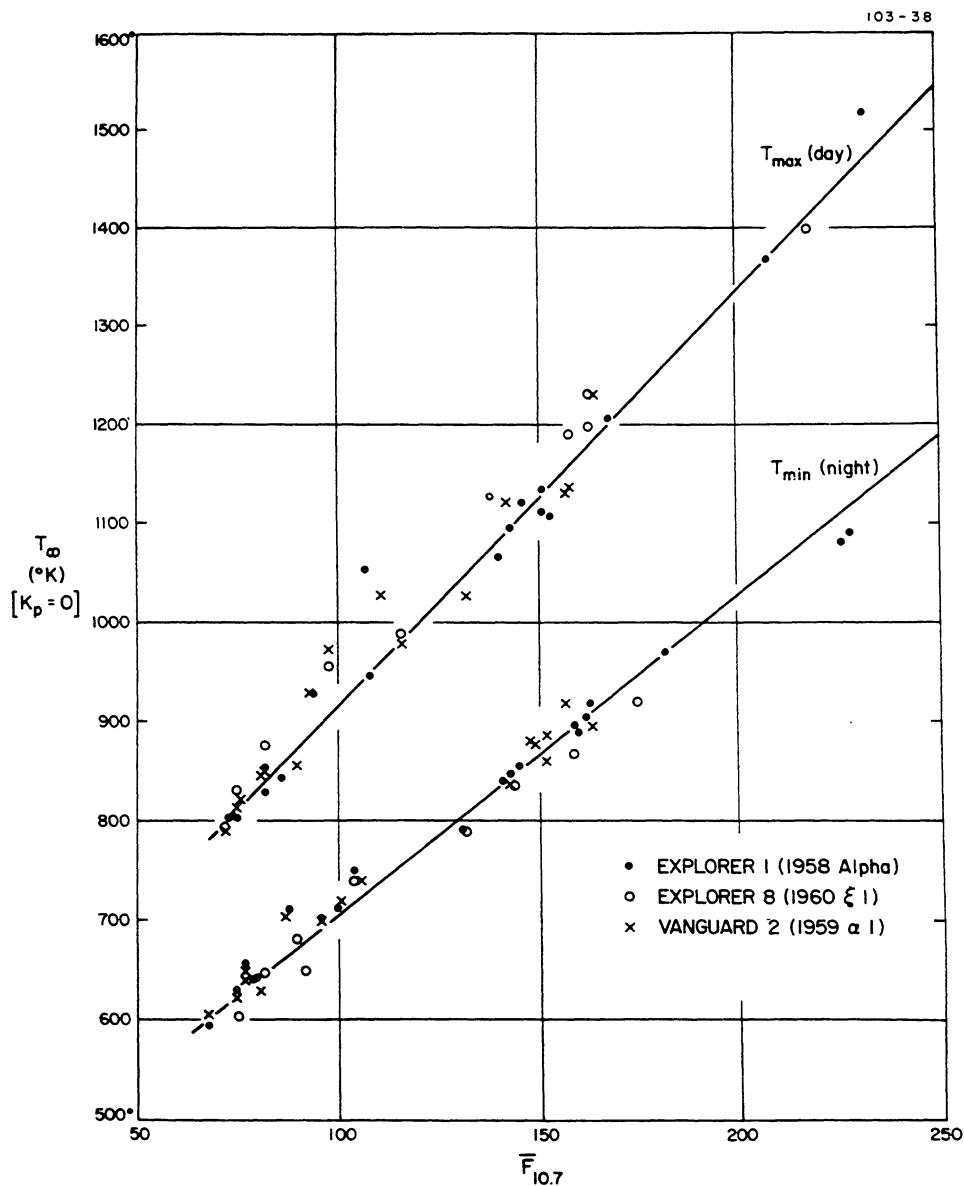

Figure 5. Global nighttime minimum and daytime maximum exospheric temperatures derived, through the use of the present models, from the densities obtained from the drag of three artificial satellites, plotted against the smoothed 10.7-cm solar flux  $\bar{F}_{10.7}$ . To obtain the data points, all variations except the diurnal variation were suppressed by using the equations associated with the models. The straight line through the minimum temperatures is represented by the equation  $T_{\min} = 379 + 3.24 \bar{F}_{10.7}$  [see eq. (14)]; the one through the maxima, by  $T_{\max} = 1.30 T_{\min}$ .

$T_{\infty} = 379^{\circ} + 3.24 \bar{F}_{10.7}$  [the first part of eq. (14)]; the one through the day-time maxima is represented by  $T_M = 1.30 T_{\infty}$ .

The effect of solar activity on atmospheric density is illustrated in Figures 6 and 7, which both show results from the drag analysis of the Explorer 1 satellite (1958 Alpha). Ten-day means of the density, and of the temperature derived from it through the use of models, are shown in Figure 6. In this figure, the periodic oscillations, with a period of 300 days at the beginning and 200 days at the end, are caused by the diurnal variation, as the perigee of the satellite slowly moves from night into day and back again into night. When these oscillations are mentally removed, we remain essentially with an 11-year variation that parallels that of the smoothed 10.7-cm solar flux, shown at the bottom of the figure. A comparison of the temperature and density variations at sunspot maximum (1958 to 1959) and sunspot minimum (1963 to 1965) clearly shows the dependence of  $d\rho/dT_{\infty}$  on  $T_{\infty}$  illustrated in Figure 4.

Figure 7 shows an 800-day section of the curves of Figure 6 in greater detail, with individual observations rather than 10-day means. Here the 27-day oscillations caused by the sun's rotation are clearly visible in the density data, and the modulation caused by the semiannual variation can be discerned. The apparent irregularities in the normalized diurnal-variation curve, which was computed from the models, are caused by the rapid motion, back and forth in latitude, of the perigee of the satellite.

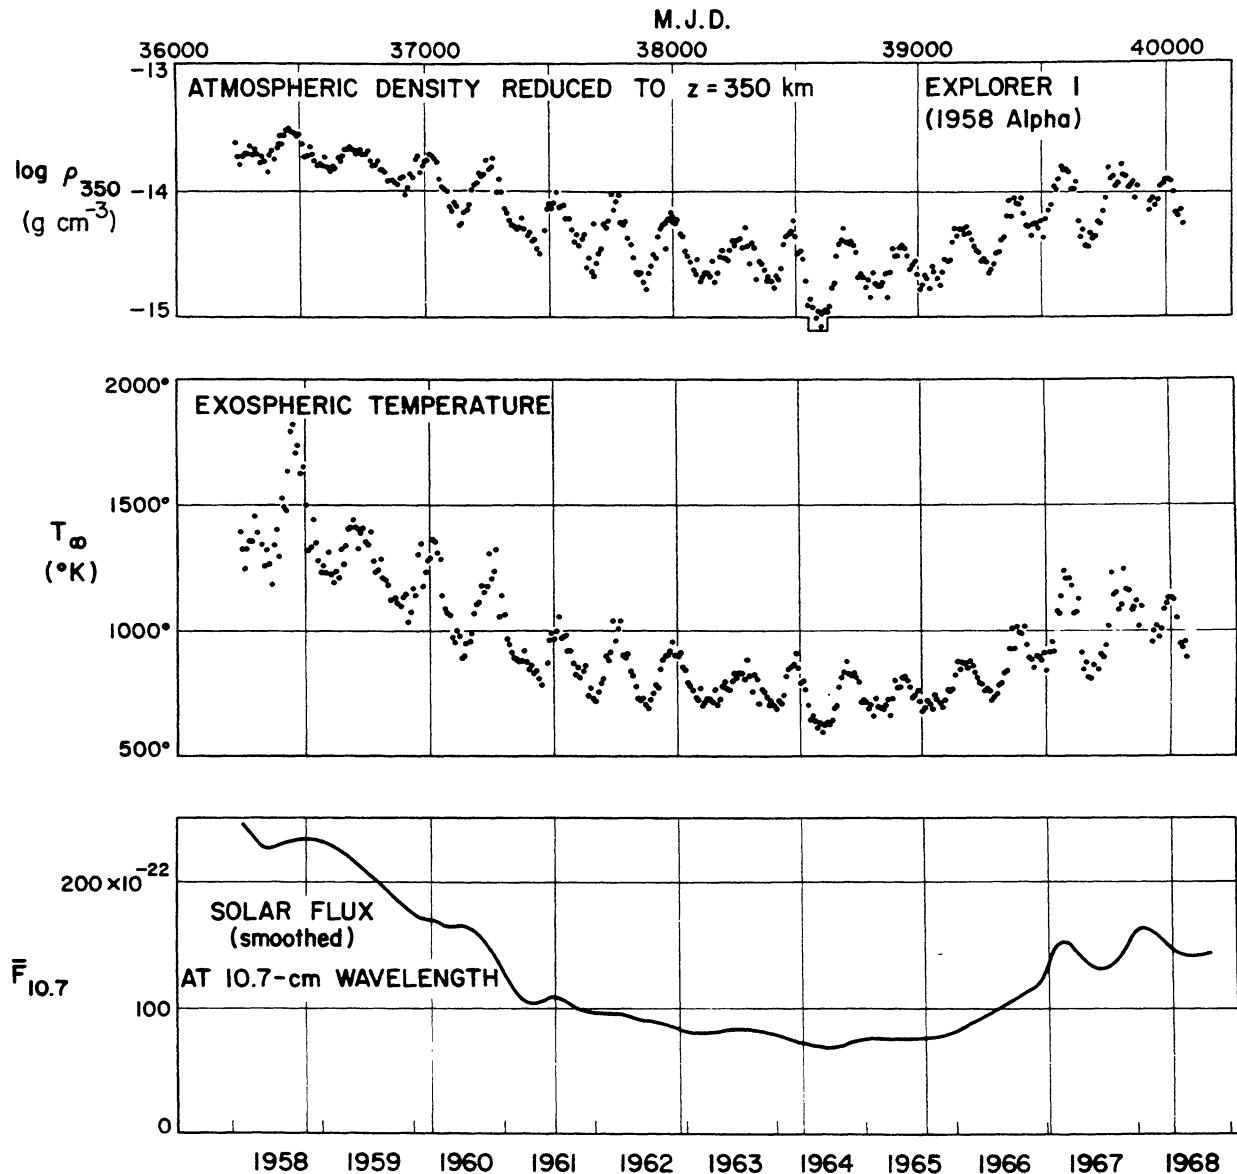

Figure 6. Ten-day means of the densities obtained from the drag of the Explorer 1 satellite and of the exospheric temperatures derived from them through the use of the J70 models. Since the purpose of this figure is to illustrate the variations of density and temperature with the solar cycle (see bottom curve), it was not deemed necessary to redo the temperature diagram by means of the present models; the difference would be hardly noticeable. M. J. D. is the Modified Julian Day (J. D. minus 2 400 000.5).

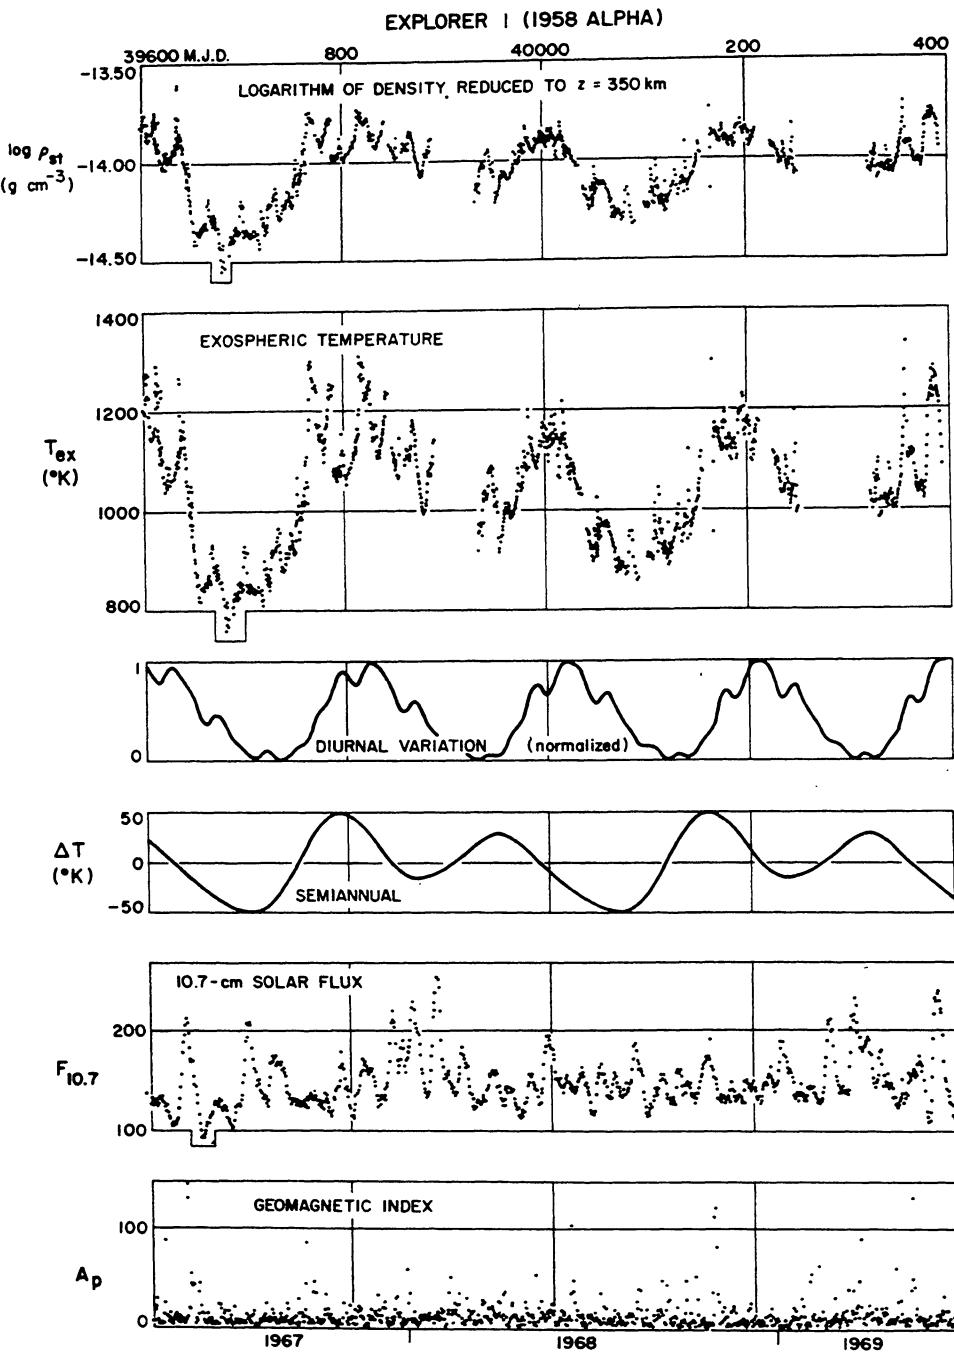

Figure 7. Densities obtained from the drag of the Explorer 1 satellite and exospheric temperatures derived from them by use of the J70 models. Since the purpose of this figure is to illustrate the 27-day oscillations and the geomagnetic effect superimposed on the diurnal variation, it was not deemed necessary to redo the temperature diagram by use of the present models; the difference would be hardly noticeable. The schematic diagrams of the diurnal and semiannual variations are also from J70.

## 7. THE DIURNAL VARIATION

Densities derived from satellite drag show a maximum around 2 p.m. local solar time (L.S.T.) at a latitude roughly equal to that of the subsolar point; the minimum occurs around 3 a.m. at about the same latitude with opposite sign. Thus, if we consider the atmosphere above a particular locality, the diurnal variation will undergo a seasonal change; this change, however, can be incorporated into a global description of the phenomenon by a set of suitable empirical equations (Jacchia, 1965b). The purpose of these equations is to represent the density variations by use of static atmospheric models. To this effect it appears necessary to use the temperature as an auxiliary parameter, but it must be understood that this "temperature" has no claim to accuracy, since consistency between temperature and density variation cannot be achieved, on a diurnal time scale, through static models.

We shall assume that the maximum daytime exospheric temperature  $T_M$  occurs at a latitude  $\phi$  equal to the sun's declination  $\delta_\odot$ , and the minimum temperature  $T_c$  [see eq. (14)] at latitude  $-\delta_\odot$ . At any other latitude  $\phi$ , the daytime maximum temperature  $T_D$  will be smaller than  $T_M$  and the nighttime minimum temperature  $T_N$  larger than  $T_c$ . Figure I shows the relation between the 10.7-cm solar flux on the one hand, and  $T_c$  and  $T_M$  as determined on the basis of the present models from the drag of three low-inclination satellites over a complete solar cycle.

The maximum and minimum temperatures  $T_D$  and  $T_N$  can be conveniently represented by the following equations (Jacchia, 1965b):

$$\begin{aligned} T_D &= T_c(1 + R \cos^m \eta) , \\ T_N &= T_c(1 + R \sin^m \theta) , \end{aligned} \quad (15)$$

where

$$\eta = \frac{1}{2} |\phi - \delta_{\odot}| ,$$

$$\theta = \frac{1}{2} |\phi + \delta_{\odot}| .$$

The temperature  $T_{\ell}$  at any given point can be expressed as a function of the hour angle H of the sun (the local solar time, counted from upper culmination). Let us write

$$T_{\ell} = T_N (1 + A \cos^n \frac{\tau}{2}) , \quad (16)$$

with

$$A = \frac{T_D - T_N}{T_N} = R \frac{\cos^m \eta - \sin^m \theta}{1 + R \sin^m \theta}$$

and

$$\tau = H + \beta + p \sin(H + \gamma) , \quad (-\pi < \tau < \pi) ,$$

where  $\beta$ ,  $\gamma$ , and  $p$  are constants. It should be remembered that  $T_{\ell}$ , which is derived from  $T_c$ , is referred to  $K_p = 0$ .

The constant  $\beta$  determines the lag of the temperature maximum with respect to the sun's culmination, while  $p$  introduces in the temperature curve an asymmetry, whose location is determined by  $\gamma$ . Replacing  $T_D$  and  $T_N$  from equation (15), we can write

$$T_{\ell} = T_c (1 + R \sin^m \theta) \left( 1 + R \frac{\cos^m \eta - \sin^m \theta}{1 + R \sin^m \theta} \cos^n \frac{\tau}{2} \right) . \quad (17)$$

Densities derived from satellite drag are best represented by use of the following parameters:

$$\begin{aligned} m &= 2.2 , & \beta &= -37^\circ , \\ n &= 3.0 , & p &= +6^\circ , \\ R &= 0.3 , & \gamma &= +43^\circ . \end{aligned}$$

There is some evidence that the shape of the diurnal density curve changes with height (Jacchia, 1970b) and with solar activity; present data, however, are insufficient to establish the rules of this variation with assurance, and therefore we have assumed that the parameters that fix the shape of the curve are constant.

Concerning the parameter R, which fixes the relative amplitude of the temperature variation, there is no a priori reason why it should be a constant. In a first analysis (Jacchia and Slowey, 1968), it was found that R was somewhat larger in 1959 to 1963 and smaller in 1964 to 1966, without any obvious relation to the solar cycle. Subsequently (Jacchia, 1970c), the suspicion arose that the variation of R followed that of solar activity with a lag of 1 to 2 years, in phase with the yearly means of the geomagnetic index  $K_p$  — a rather disturbing finding, since it implied a strong contribution of the solar wind to the heating of the atmosphere. More recent data on R, from the years 1969 and 1970, have failed to confirm this finding, and a new analysis of R using the present atmospheric models as a basis seems to indicate that, if there is a variation of R, it is not related to the solar cycle (see Figure 5). Under these circumstances, it seems best to make R independent of time or solar activity.

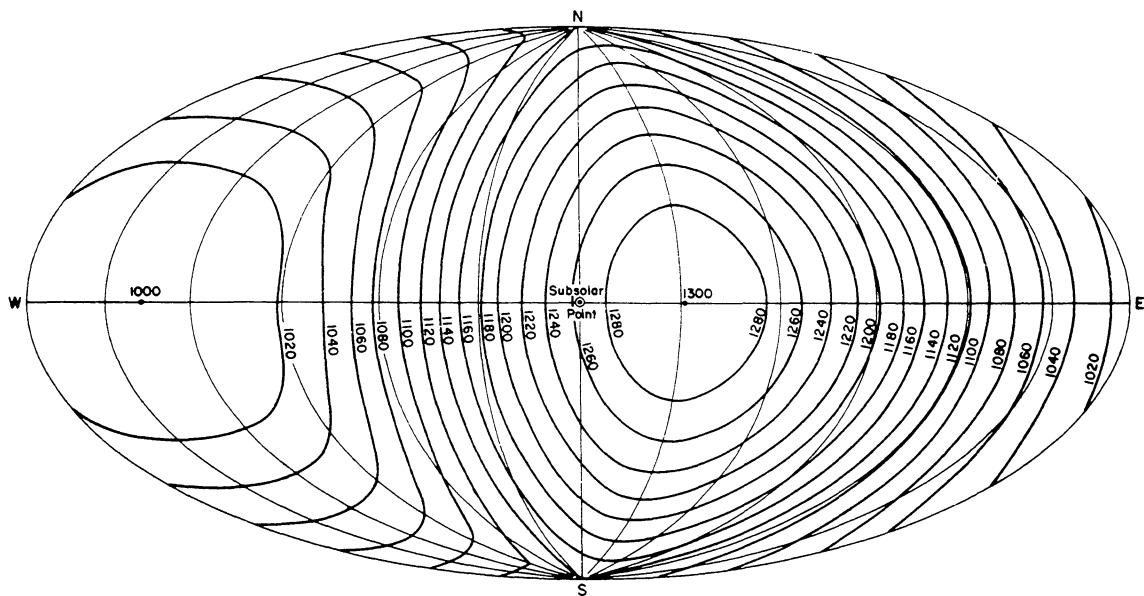

Recently, we found that there is a systematic change of R with height. The value  $R = 0.3$  we have given refers to a height of about 400 km. At 600 km, however, we find that if we use this value of R, we are left with systematic density residuals, negative at night and positive in daytime, which can be corrected by using a larger value of R (0.35) and a lower value of  $T_c$ , such as to leave the mean daily temperature unchanged. The residuals are even larger at 900 km, always with the same characteristics, and require a value  $R = 0.4$  with a correspondingly lower  $T_c$  for their correction. At 1100 to 1200 km, however,  $R = 0.3$  again gives satisfactory results. We believe that this change of R is not a real variation of  $T_M/T_c$  with height but simply reflects the inadequacy of static models to represent the diurnal density variation throughout the whole atmosphere. If we consider the curve that represents the real diurnal temperature variation at a given height above

a given geographic location for a given day and if we select on it two points, one on the ascending branch (morning) and one on the descending branch (evening) such that they have the same ordinate (temperature), we shall find that in a truly dynamical model the two temperature profiles corresponding to the two instants are different, although they cross at our given point. In static models, however, the two profiles are identical. This difference in behavior is bound to result in discrepancies such as the one we have described. It is significant that in the CIRA 1965 models, which were constructed on a dynamical basis, the amplitude of the diurnal density variation increases with height faster than it does in the static models (Jacchia, 1968).

Table 1 gives the ratio  $T_{\ell}/T_c$ , multiplied by the factor 1000, as a function of L.S.T. (counted from midnight) and latitude [computed from eqs. (15) and (16)]. According to this model, the hours of minimum and maximum of the daily density variation are independent of latitude and are  $2.87^{\text{h}}$  and  $14.08^{\text{h}}$  L.S.T., respectively. A graphical representation of the resulting temperature distribution is shown in Figure 8 for the equinoxes and the northern summer solstice.

A certain degree of smoothing must be expected in the daily density variation as determined from satellite drag. The smoothing occurs not only because the drag is experienced over a considerable arc of the orbit but also because the slow motion of the perigee with respect to the sun prevents the determination of individual diurnal density oscillations. It takes, on the average, 200 to 300 days for the perigee of a satellite orbit to move from night into daylight and into night again, so the diurnal oscillation as seen through satellite drag resembles an oscillatory phenomenon studied by stroboscopic means (Figures 6 and 7). During the average synodic cycle of 200 to 300 days, the perigee of a satellite moves back and forth in latitude (and therefore from summer to winter) several times, and there are all sorts of variations with solar and geomagnetic activity that must be suppressed if we want to have a clean picture of the diurnal variation.

Temperatures derived from nitrogen profiles obtained from six rocket firings from Cape Kennedy on January 24, 1967 (Taeusch et al., 1968),

EXOSPHERIC TEMPERATURE DISTRIBUTION AT NORTHERN SUMMER SOLSTICE

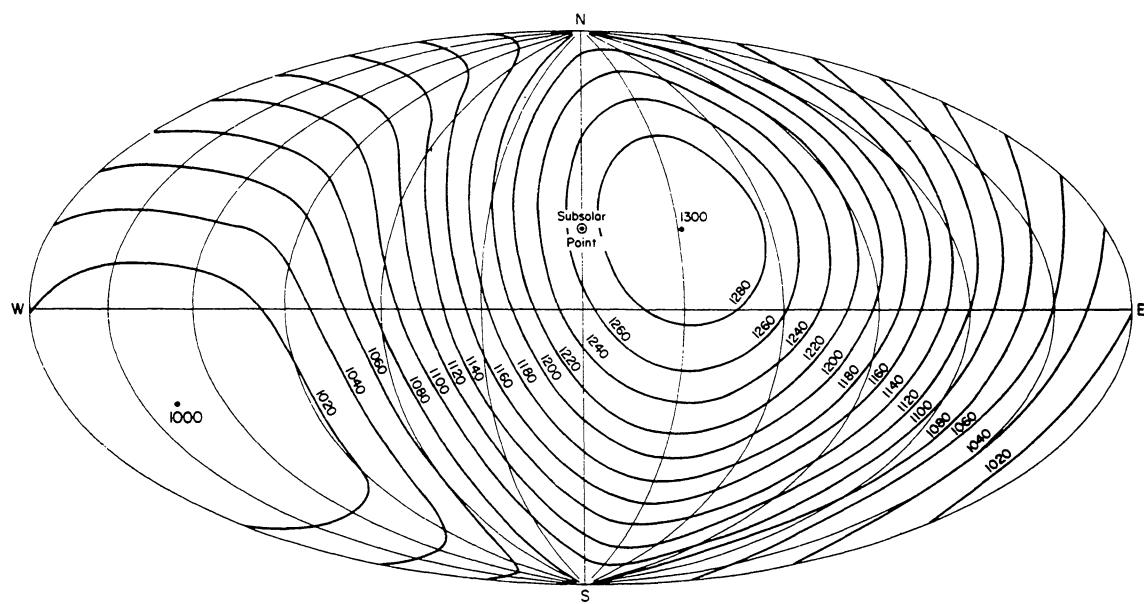

Figure 8. Exospheric isotherms ( $^{\circ}\text{K}$ ) above the globe, computed from equations (15) and (16), for the case when the minimum temperature is  $1000^{\circ}\text{K}$ . Aitoff's equal-area projection; meridians of local solar time and parallels of latitude are drawn  $30^{\circ}$  apart. Top, equinoxes; bottom, northern summer solstice.

essentially agree in amplitude and phase with those of the present model. Also in good agreement with the model are the temperature ranges obtained from thermosphere probes (Spencer *et al.*, 1966), from mass-spectrometer data on Explorer 17 (Reber and Nicolet, 1965) and Explorer 32 (Newton, 1969), and from EUV absorption (Hall *et al.*, 1967).

Temperatures in the neutral atmosphere can be inferred from Thomson-scatter measurements (Carru, Petit, and Waldteufel, 1967; Carru and Waldteufel, 1969; McClure, 1969), and much has been written about the discrepancies between the diurnal temperature variations as derived by this method and those derived from densities by means of existing models. The Thomson-scatter temperatures are essentially ion temperatures and refer to a height of about 300 km. They generally show secondary oscillations that cannot entirely be accounted for by geomagnetic activity. Occasionally, however, the temperature curves are relatively smooth, and in such cases they seem to follow quite closely the temperatures predicted by the present models, as we can see from Figure 9. The data plotted in this figure are hourly running means, taken at 10-min intervals, of temperatures measured by Carru and Waldteufel (1969). The continuous curve represents the temperature predicted by the present models; the small irregularities in the curve are caused by the geomagnetic effect. As can be seen, the agreement, on the whole, is extraordinarily good. A systematic deviation from the predicted curve is generally present around the time of maximum, in the afternoon. The temperatures determined by Thomson-scatter techniques seem to linger at maximum a little longer, dropping only after 4 p.m., while the predicted maximum occurs shortly after 2 p.m. As can be seen from Figure 9, however, this particular discrepancy is not serious and can be explained by the smoothing, of which we spoke earlier, inherent in drag measurements, and therefore also in the equations that represent the diurnal variation in the models. Apart from this minor discrepancy, the temperature curve seems to lag about 30 min behind the density curve in the 12-hour interval from 6<sup>h</sup> to 18<sup>h</sup>. Although the lag is not so serious as it would appear if we simply compare the times of the maxima of the two curves, it is somewhat surprising because of its direction: Offhand, one would expect the density curve to lag

behind the temperature curve, as in the CIRA 1965 models. Speculations on the mechanism by which such a lag can be achieved have recently appeared in the literature (see, for example, Rishbeth, 1969). Although the diurnal temperature variations as obtained by incoherent-scatter techniques can be considered to be in fair agreement, generally speaking, with those given by the present models, there seems to be some discrepancy in the variation of the amplitude with the seasons (Waldteufel, 1970).

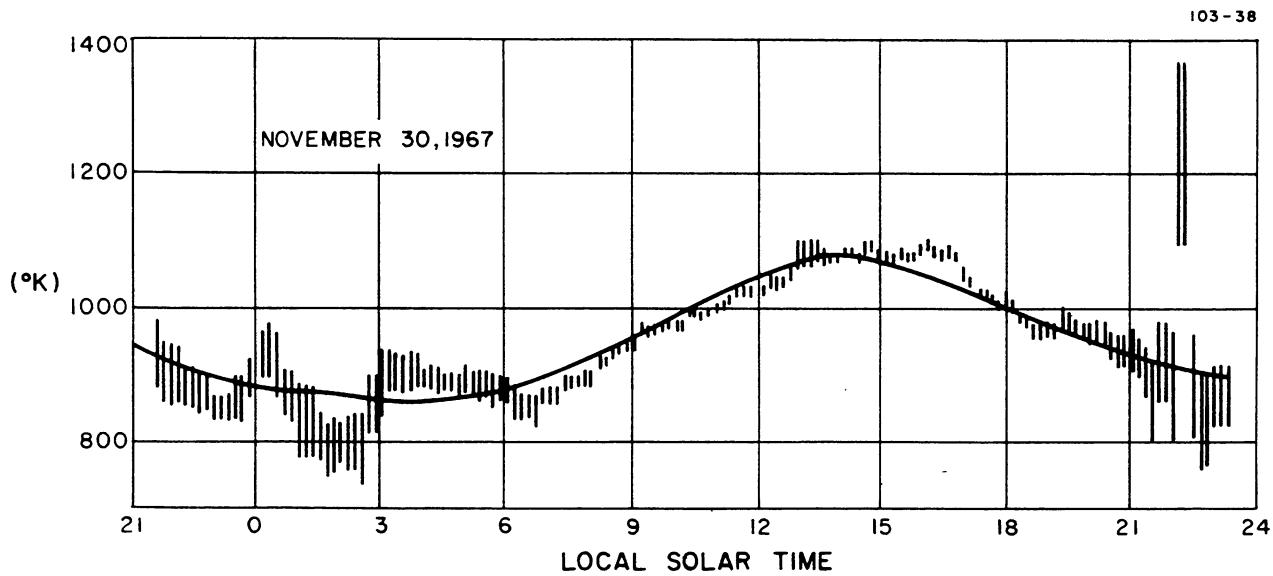

Figure 9. Atmospheric temperatures obtained on November 30, 1967, by Carru and Waldteufel (1969) by use of Thomson-scatter techniques, compared with temperatures predicted by the present models for a height of 300 km (solid line).

## 8. VARIATIONS WITH GEOMAGNETIC ACTIVITY

Recent high-resolution satellite measurements of temperatures with Doppler techniques applied to the  $\lambda$  6300 oxygen line (Blamont and Luton, 1971) and of densities with accelerometers (DeVries, 1971) have made it increasingly clear that the geographic distribution of temperatures and densities at the onset of a geomagnetic disturbance and its variation in the course of the development of the disturbance follow a rather complex pattern, of which the orbital-drag method, with its limited resolution, can give only a very blurred picture. It would seem that at the start of a magnetic storm, there is an immediate increase of temperature and density in the thermosphere above part of the auroral belt and that the atmospheric perturbation propagates, reaching the equatorial regions, considerably weakened, some 7 hours later. The transport of energy from high to low latitudes during magnetic storms is corroborated by observations of winds (Smith, 1968) and gravity waves (Newton, Pelz, and Volland, 1969; Champion, Marcos, and McIsaac, 1970) in the thermosphere.

The highest time resolution that can be achieved by orbital-drag analysis of satellites is one density value per satellite revolution (90 to 120 min), and this value is not that of the density at a precise location, but rather a density averaged over a sizable orbital arc centered around the perigee point. Clearly, even under the most favorable conditions, a great deal of smoothing is introduced into the results. Yet, even satellite-drag data can establish, in broad outlines, the main features of the atmospheric perturbation that follows a magnetic disturbance: the greater intensity at high latitudes (Jacchia and Slowey, 1964; Jacchia, Slowey, and Verniani, 1967; Roemer, 1971) and the increase in the lag time from high to low latitudes [Jacchia *et al.* (1967); however, Roemer (1971) failed to detect this feature]. Since no workable model has been produced to date to give a quantitative representation of the high-resolution data, we shall have to be content with models based on orbital-drag measurements. Although they will not be adequate for comparisons with instantaneous data, they should be helpful in satellite-drag work.

Since the characteristic time of geomagnetic disturbances is hours rather than days, static models cannot be expected to represent correctly both temperature and density variations, so we must apply to the equations that describe the phenomenon the same reservations we applied to the equations for the diurnal variation (Section 7). The equations that have been most widely used (Jacchia, 1965a; Jacchia *et al.*, 1967) relate the exospheric temperature to the planetary geomagnetic index  $a_p$  or to its quasi-logarithmic equivalent  $K_p$ ; thus, implicitly, they make the assumption (*a priori* unlikely to be true) that in the process of atmospheric heating, the shape of the temperature profiles remains unchanged with respect to the basic models. Although these formulas seem to fit drag data reasonably well at heights greater than 200 km, we find that the density variations they predict at lower heights are too small (Zirm, 1964; King-Hele and Walker, 1969a, b; Schusterman, 1970). This means, in all probability, that the temperature profiles in the lower thermosphere are distorted by geomagnetic heating with respect to those of the basic models, in the direction of higher temperatures. Eventually it should be possible to determine this distortion on the basis of observations, but the task of computing densities from temperature profiles with shapes that change with geomagnetic activity presents practical problems of considerable difficulty. As a stopgap, we have recently resorted to using a hybrid formula, in which part of the density variation is obtained by altering the boundary density as a function of  $K_p$  and the rest by changing the exospheric temperature just as in the old formulas. The density part of the equation is intended to compensate roughly for the distortion in the temperature profile at lower heights. As a result of this artifice, the variations in the exospheric temperature become smaller — but this would also be true if we actually used the distorted temperature profile.

In view of this confused situation, we shall give here formulas based on changes in the exospheric temperature alone, as well as the hybrid formula. It must be remembered that if the former are used, the density variations below 200 km will be too small; on the other hand, if the hybrid formula is used, the density variations below 200 km will be represented somewhat better (except, perhaps, near the 90-km boundary), but the exospheric temperatures may be in error.

Jacchia *et al.* (1967) gave the following formula for the geomagnetic effect on the temperature:

$$\Delta T_{\infty} = 28^{\circ} K_p + 0.03 \exp(K_p) , \quad (18)$$

in which  $K_p$  is the 3-hour geomagnetic planetary index. The time lag  $\Delta t$  of the atmospheric variation behind the geomagnetic disturbance was given as  $7.2 \pm 0.3$  hours at latitude  $25^{\circ}$  and  $5.8 \pm 0.5$  hours at latitude  $65^{\circ}$ , with an overall mean of  $6.7 \pm 0.3$  hours. It was also found that at  $65^{\circ}$  the amplitude of the variation was some 10 to 20% greater than at  $25^{\circ}$ .

Roemer (1971) modified equation (18) to incorporate a latitude dependence into the first coefficient:

$$\Delta T_{\infty} = (21.4 \sin \phi + 17.9) \bar{K}_p + 0.03 \exp(\bar{K}_p) , \quad (19)$$

where  $\bar{K}_p$  is the 0.4-day mean of the original 3-hourly planetary index  $K_p$ . This formula reduces to equation (18) when the latitude  $\phi$  is  $28^{\circ}$ . Roemer found an average time lag  $\Delta t = 5.5 \pm 0.3$  hours but could not find any variation of  $\Delta t$  with latitude. He did, on the other hand, find a sinusoidal variation of  $\Delta T_{\infty}/K_p$  with local time, with a maximum at 3 a.m. larger by a factor 1.30 with respect to a 3 p.m. minimum.

The hybrid formula we find best to represent density variations below 200 km is as follows:

$$(a) \Delta \log_{10} \rho = 0.012 K_p + 1.2 \times 10^{-5} \exp(K_p) ;$$

$$(b) \Delta T_{\infty} = 14^{\circ} K_p + 0.02 \exp(K_p) . \quad (20)$$

To obtain the total density variation from the rest value  $K_p = 0$  to that corresponding to a given value of  $K_p$ , the density variation given by equation (a) must be added to that resulting from equation (b).

As we said earlier in this section, all these equations give only a smoothed version of the real variations, for which no model exists, and should be valid only for comparisons with satellite-drag data. Even in this case, however, the formulas should not be used with the original 3-hourly  $K_p$  indexes but rather with a smoothed  $\bar{K}_p$  index, in which the smoothing is commensurate with the resolution of the observed data.

Corrections for the geomagnetic effect according to equation (18) are given in Table 2a; Table 2b gives corrections according to equations (20). As an illustration of the geomagnetic effect, we have plotted in Figure 10 the temperature residuals, obtained through the use of static models when all other variations are suppressed, from the drag-derived densities for six satellites with perigee heights from 338 to 1001 km, in a 3-week interval in May to June 1967 covering one of the greatest magnetic storms on record. The bottom diagram shows, for comparison, temperature residuals  $\Delta T$  computed from equation (18).

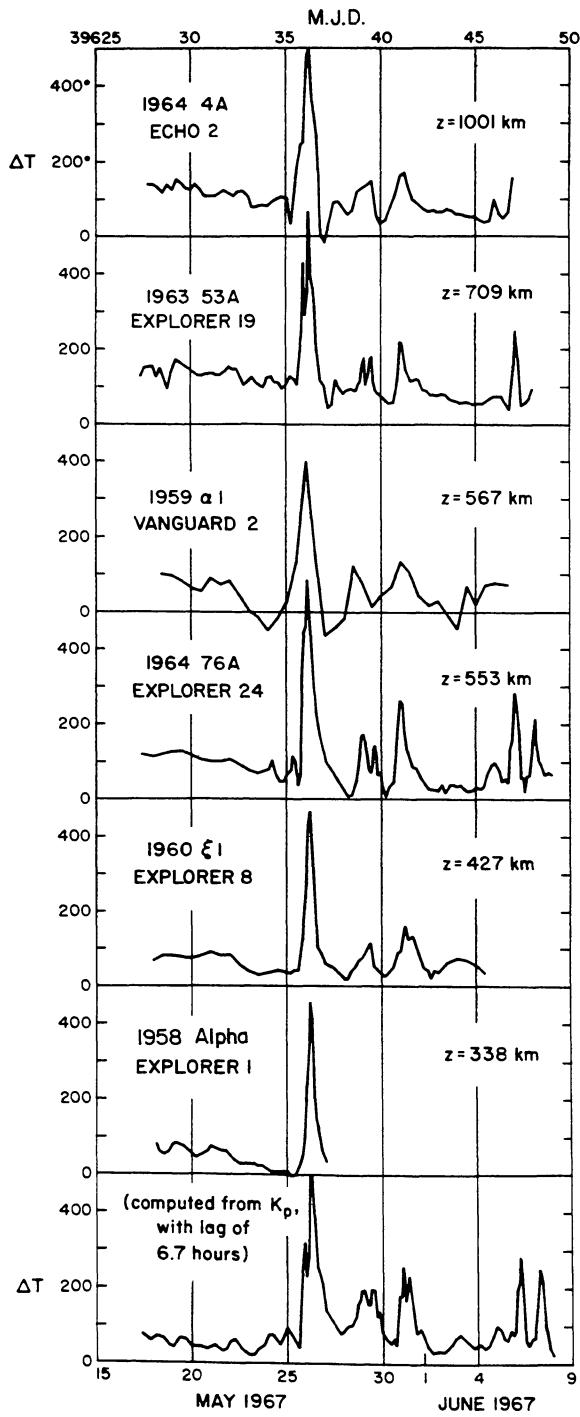

Figure 10. The geomagnetic effect as derived from the drag of six satellites in May and June 1967. The plotted  $\Delta T$ 's are temperature residuals from the models when all variations except the geomagnetic effect have been taken into account. The diagram at the bottom shows  $\Delta T$  as computed from equation (18). M.J.D. is the Modified Julian Day (J.D. minus 2 400 000.5).

## 9. THE SEMIANNUAL VARIATION

The semiannual density variation observed in the thermosphere and lower exosphere is a rather puzzling feature for which no satisfactory explanation has yet been found. Temperature variations are the immediate cause of the solar-activity effect, the diurnal variation, and the geomagnetic effect. While attempting to find a way of representing the semiannual variation in analytic form for the J65 models, we thought it rather logical to try to link it also to temperature variations, and the formula we found seemed to work for the data we had available at that time, i.e., densities from the drag of satellites with perigee heights between 250 and 650 km. The amplitude of the temperature variation seemed to be dependent on solar activity, and this seemed further to justify the assumed dependence on temperature variations.

Difficulties, however, soon became apparent. Cook and Scott (1966) and Cook (1967, 1969a) found that near sunspot minimum the amplitude of the semiannual density variation at 1100 km derived from the drag of the Echo 2 and the Calsphere satellites was much larger than that predicted on the basis of the J65 formula. At that height, according to the models, in 1964 to 1965 any temperature variation would have resulted in extremely small density variations, because of the near-balance of the helium variations in phase with the temperature and the hydrogen variations in antiphase. At the time the variation should have been no larger than 6%, the observed variations reached a factor of 2. In 1966, when solar activity rose toward its maximum (and hydrogen became a negligible constituent at that height), the discrepancy became smaller and almost disappeared.

With the launching of longer lived satellites with low perigee heights, another discrepancy became evident for heights below 200 km. Also here, at heights of 150 to 200 km, the observed variation was larger than that predicted by J65 (King-Hele and Hingston, 1967, 1968; King-Hele, 1967; King-Hele and Walker, 1970). Initially, we attributed this discrepancy to the fact

that in the J65 models constant boundary conditions were assumed at 120 km, where fairly large density variations with temperature actually occur: The reasoning was that, approaching 120 km, the computed density variations should have proved too small. More recent models, however (Jacchia, 1970a), in which the constant-boundary conditions were moved to 90 km, also proved inadequate to represent the observed semiannual density variation in the 150- to 180-km region. Cook (1969b) actually found that the semiannual variation, still in phase with that in the thermosphere and exosphere, can be discerned even at 90 km, which is a near-isopycnic level at which all other density variations nearly vanish (Groves, 1970). The range in density found by Cook at 90 km amounts to about 30%, but a reanalysis of his data by this writer, eliminating high-latitude measurements, which are affected by annual (seasonal) variations, reduces the range to 15%, which is still a respectable amount.

Decreasing the amount of hydrogen in the atmosphere would increase the computed amplitudes at 1100 km, but then the computed total density is too low at sunspot minimum. Besides, hydrogen densities from Balmer a observations (Tinsley, 1970) would indicate a larger, not a smaller, hydrogen concentration. Also, any tampering with the hydrogen concentration in the models would not cure the discrepancies observed at heights below 200 km.

An obvious way out of all these difficulties is to assume that the semi-annual density variations are not caused by temperature variations. The main reason for clinging to a model based on temperature variations was the apparent dependence of the amplitude of the diurnal variation on solar activity. As it turns out, however, this is really a built-in variation, because at any given height in the heterosphere the change of density with temperature  $d\rho/dT$  is strongly dependent on the temperature T itself (see Figure 4). Therefore, even a density variation with constant amplitude throughout the solar cycle, if interpreted as a thermal variation, would yield a temperature amplitude dependent on the phase of the solar cycle. Reanalyzing the density variations obtained from the orbital drag of six satellites in the interval 1958 to 1970, we find that this is precisely the case (Jacchia, 1971): The

amplitude of semiannual density variation, although strongly height dependent and variable from year to year (Figure 11), does not seem to be related to solar activity.

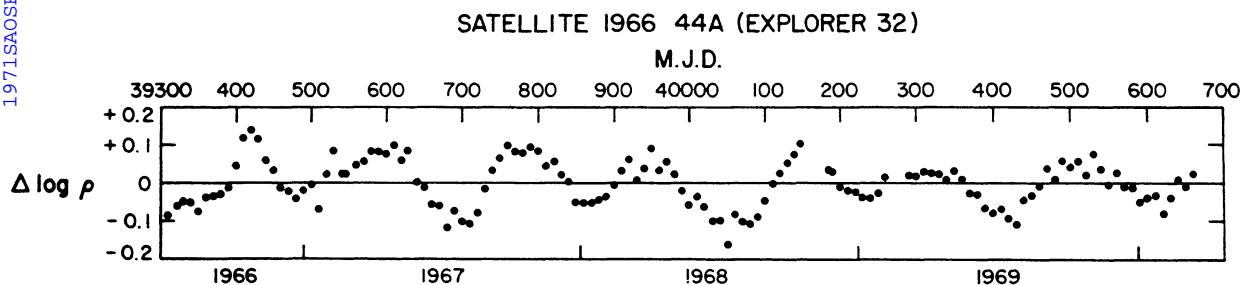

Figure 11. The semiannual density variation as derived from drag analysis on Satellite 1966 44 A (Explorer 32). All other variations have been suppressed by using the appropriate equations. M. J. D. is the Modified Julian Day (J. D. minus 2 400 000.5).

We deem it best, therefore, to express the semiannual density variation in the form

$$\Delta \log_{10} \rho_{\text{semiannual}} = f(z) g(t) , \quad (21)$$

where  $g(t)$  represents the average density variation as a function of time in which the amplitude (i.e., the difference in  $\log \rho$  between the principal minimum in July and the principal maximum in October) is normalized to 1, and  $f(z)$  is the relation between the amplitude and the height  $z$ . We found the following equations to fit the data best:

$$f(z) = (5.876 \times 10^{-7} z^{2.331} + 0.06328) \exp(-2.868 \times 10^{-3} z) \quad (z \text{ in km}) ;$$

$$g(t) = 0.02835 + 0.3817 [1 + 0.4671 \sin(2\pi\tau + 4.137)] \sin(4\pi\tau + 4.259) , \quad (22)$$

with

$$\tau = \Phi + 0.09544 \left\{ \left[ \frac{1}{2} + \frac{1}{2} \sin(2\pi\Phi + 6.035) \right]^{1.650} - \frac{1}{2} \right\} ,$$

1971SAOSSR.332.....J where  $\Phi$  is the phase of the semiannual variation, i.e., approximately the number of days elapsed since January 1 divided by the duration of the tropical year in days. A more rigorous expression, better suited for computer purposes, is

$$\Phi = (t - 36204)/365.2422 , \quad (23)$$

where  $t$  is time expressed in Modified Julian Days (M.J.D. = Julian Day minus 2 400 000.5). M.J.D. 36204 corresponds to January 1, 1958. The absolute term (0.02835) in the expression for  $g(t)$  has the purpose of making  $\int g(t) dt = 0$  over one cycle of the variation. The functions  $f(z)$  and  $g(t)$  are tabulated in Table 3.

It should be understood, of course, that even though temperature variations are apparently not the primary cause of the semiannual density variations, these must be accompanied by some temperature changes, however small. The determination of such temperature changes must wait, however, for better observations or, more likely, for dynamical models of the phenomenon.

## 10. SEASONAL-LATITUDINAL VARIATIONS OF THE LOWER THERMOSPHERE

In the present models we have assumed that temperature and density are constant at 90 km all over the globe. In reality, seasonal-latitudinal variations are observed at that height — fairly large in temperature, although relatively small in density. All the variations we have described so far could be taken into account with a fair degree of approximation by operating on the exospheric temperature; such a procedure is obviously impossible for the seasonal-latitudinal variations, for which it is necessary to operate on the lower boundary conditions. However reluctantly, the decision to keep the lower boundary conditions constant had to be taken to prevent the models' becoming unmanageable in their complexity.

An attempt was made in the U. S. Standard Atmosphere Supplements, 1966 (COESA, 1966) to effect a smooth junction between the densities of lower-thermosphere models with seasonal variations and the densities of upper-atmosphere models computed by use of constant boundary conditions at 120 km. The models were limited to a fixed, intermediate latitude and to three seasons (summer, winter, and spring/fall); any greater detail would have entailed a prohibitive proliferation of tables. If we wanted to have models for every month at  $15^\circ$  intervals in latitude, the number of models would increase by a factor of 84!

The amplitude of the seasonal-latitudinal density variations increases very rapidly between 90 and 100 km; the maximum amplitude is apparently reached between 105 and 120 km; above this height it must decrease quite rapidly because above 160 km there seem to be no appreciable seasonal-latitudinal variations other than those involved in the global pattern of the diurnal variation. This means that the temperature variations, which at 100 km are in phase with the density variations, must undergo a phase inversion around 110 km and reach a maximum amplitude, in opposite phase with respect to the densities, somewhere around 150 km. While it is relatively easy to represent the density variations in analytical, and even in tabular,

form, it would be prohibitively laborious to do the same thing for the temperatures. We thought the best that could be done was to give formulas for computing the seasonal-latitudinal variations in density, ignoring the temperature variations.

The equation we present here is an attempt to fit the seasonal variations as derived by Champion (1967) and Groves (1970). We find that the values of  $\log \rho$  given by the models must be corrected by adding a quantity  $\Delta \log \rho$  given by

$$\Delta \log_{10} \rho = 0.014(z - 90) \exp[-0.0013(z - 90)^2] \frac{\phi}{|\phi|} \sin(2\pi\Phi + 1.72) \sin^2 \phi , \quad (24)$$

where  $\phi$  is the geographic latitude,  $z$  the height in kilometers, and  $\Phi$  the phase as defined by equation (23). We can write this formula as

$$\Delta \log_{10} \rho = S \frac{\phi}{|\phi|} P \sin^2 \phi ,$$

with  $S = 0.014(z - 90) \exp[-0.0013(z - 90)^2]$  and  $P = \sin(2\pi\Phi + 1.72)$ . Tabulations of  $S$ ,  $P$ , and  $\sin^2 \phi$  are given in Table 4.

There are no reliable data on the seasonal-latitudinal variation above 120 km. In the J70 models we adjusted the parameters of equation (24) in such a way that the logarithmic half-range  $S$  would reach a maximum of about 0.16 at 110 to 115 km and decline to one-tenth this value at 200 km. According to that formula, at 150 km we had  $S = 0.08$ , or half the maximum value. According to recent observations (Schusterman, 1970), this value is too large: At 150 km, hardly any seasonal-latitudinal variations can be discerned. Consequently, we have modified the equation so that  $S$  declines much faster for heights greater than 110 km; with the present equation, we have  $S = 0.008$  at 150 km.

## 11. SEASONAL-LATITUDINAL VARIATIONS OF HELIUM

A strong increase of helium concentration above the winter pole has been revealed by mass-spectrometer measurements (Hartmann, Mauersberger, and Müller, 1968; Kasprzak, Krankowsky, and Nier, 1968; Krankowsky, Kasprzak, and Nier, 1968; Müller and Hartmann, 1969), by observations of the intensity of the  $\lambda$  10830 resonance line of helium (Fedorova, 1967; Shefov, 1968; Tinsley, 1968), and by satellite-drag data (Jacchia and Slowey, 1968; Keating and Prior, 1968).

While the mechanism of the seasonal migration of helium is not yet clear, it is possible to establish empirical equations to describe the phenomenon. An equation we tentatively proposed in the J70 models appears to be rather unwieldy and does not respect the conservation of helium on a global scale; this resulted in a spurious semiannual variation of helium. Keating, Mullins, and Prior (1970) used, with considerable success, a formula of the type

$$\Delta \log_{10} n(\text{He}) = C \phi \delta_{\odot} ,$$

where  $\phi$  is the latitude and  $\delta_{\odot}$  the declination of the sun. For the constant  $C$ , they found the value -0.4 when  $\phi$  and  $\delta_{\odot}$  are expressed in radians; this would give a total range in  $\log n(\text{He})$  of 0.514 at the poles, corresponding to a ratio of 3.3 in  $n(\text{He})$ . This formula has the disadvantage of having a cusp in the helium distribution at the poles. We find that the seasonal density variations derived from the drag of Explorer 19 and Explorer 24 can be satisfactorily represented using the following expression for the helium variation:

$$\Delta \log_{10} n(\text{He}) = 0.65 \left| \frac{\delta_{\odot}}{\epsilon} \right| \left[ \sin^3 \left( \frac{\pi}{4} - \frac{\phi}{2} \frac{\delta_{\odot}}{|\delta_{\odot}|} \right) - \sin^3 \frac{\pi}{4} \right] . \quad (25)$$

Here  $\epsilon$  is the obliquity of the ecliptic,  $23^\circ 44$ . According to this formula, the range of the helium variation at the poles corresponds to a factor of 4.5 in  $n(\text{He})$ . Table 5 gives  $\Delta \log_{10} n(\text{He})$  as a function of  $\phi$  and of the date of the year, according to equation (25). Figure 12 shows density residuals from the drag of the Explorer 19 satellite when all variations except the helium variation are suppressed. The curve through the data points represents equation (25).

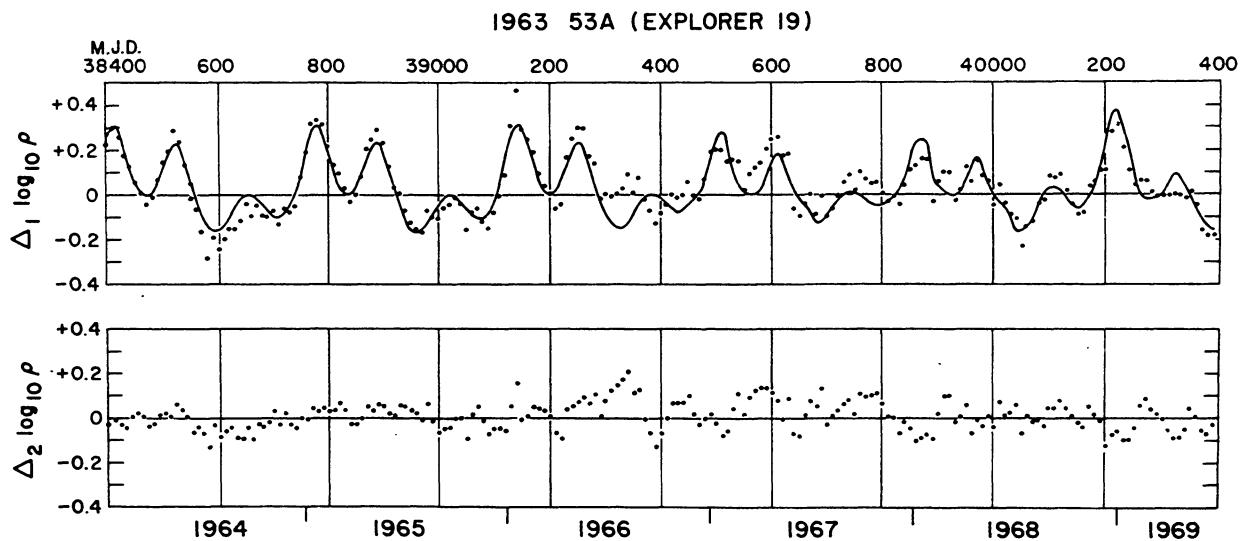

Figure 12. Observed and computed density variations caused by the helium migration, as derived from the drag on Satellite 1963 53A (Explorer 19). The data points in  $\Delta_1 \log \rho$  are density residuals from the model when all variations except the helium variation are suppressed. The solid line represents the residuals computed by means of equation (25).  $\Delta_2 \log \rho$  is the difference O-C in  $\Delta_1 \log \rho$ . M.J.D. is the Modified Julian Day (J.D. minus 2 400 000.5).

## 12. VARIATIONS IN HYDROGEN CONCENTRATION

As explained in Section 3, the hydrogen concentrations in the basic models are adopted from the theory of Kockarts and Nicolet (1962, 1963). Since the amount of neutral hydrogen in the atmosphere is primarily determined by its production and escape rates, there can be no diffusion equilibrium of hydrogen in the true sense. The computations made by Kockarts and Nicolet show, however, that above 500 km the hydrogen density profiles approximate those corresponding to diffusion equilibrium. For heights lower than 500 km, the departure from diffusion equilibrium becomes progressively larger, so we have not included hydrogen in our tables for  $z < 500$  km; for data at those heights, we must refer the user of our models to the original papers by Kockarts and Nicolet. Although not given in the tables, hydrogen concentrations at heights below 500 km were actually computed in the same manner as above 500 km and taken into account in the computation of the total density, in order to avoid any discontinuity — no matter how small — in the density profiles across the 500-km level.

On the basis of theory, it could be expected that the variations in hydrogen concentration should mirror the variations of the exospheric temperature even on a relatively small time scale. Until recently, most of the observational evidence of a variation in  $n(H)$  came from Lyman  $\alpha$  airglow measurements, which showed the existence of a diurnal variation and a variation with the solar cycle (Donahue, 1966) in the expected direction (more hydrogen at lower temperatures). Quantitative conclusions from these observations are difficult because of the variable intensity of solar Lyman  $\alpha$  (Meier, 1969). Recently, Brinton and Mayr (1971) derived the temporal variations of thermospheric  $n(H)$  from  $n(H^+)$  measured by an ion mass spectrometer on the Explorer 32 satellite in the altitude range 275 to 400 km between June 1966 and January 1967, during a period of rapid increase in solar activity accompanied by large 27-day fluctuations in the solar decimetric flux. Although assumptions had to be made regarding charge-exchange equilibrium, the results that were obtained

concerning the diurnal variation and the variation with solar activity look very reasonable and confirm a variation of  $n(H)$  with temperature in essential agreement with the variations predicted by the present models when the temperature variations with solar activity are computed from equation (14) and the diurnal temperature variations from equations (16) and (17); the observed amplitude of  $n(H)$  in the diurnal variation, however, is smaller than the predicted amplitude — a factor of 2 instead of 4.

Should the smaller amplitude of the diurnal  $n(H)$  variation be confirmed, it may prove convenient to reduce it also in the models. This can be accomplished by using for hydrogen a fictitious temperature  $T'$  that in the diurnal variation oscillates around the average daily temperature with a smaller amplitude. If, for simplicity, we assume that the average daily temperature  $\bar{T}$  is the arithmetic mean between  $T_c$  and  $T_M$  (see Section 7) and we call  $c$  the reduction factor in the amplitude, we can write

$$\begin{aligned}\bar{T} &= T_c \left(1 + \frac{R}{2}\right) , \\ T' &= \bar{T} + c (T_\ell - \bar{T}) .\end{aligned}\quad (26)$$

Large seasonal-latitudinal asymmetries in the distribution of geocoronal hydrogen seem to be indicated by Lyman- $\alpha$  observations (Donahue, 1969) and may be expected also as a consequence of the so-called "polar wind" (Banks and Holzer, 1968). A quantitative evaluation of these variations seems out of the question for the time being.

### 13. DENSITY WAVES

Density gauges on the Explorer 32 satellite have detected the existence of waves throughout the upper atmosphere in the height range from 286 (satellite perigee) to at least 510 km (Newton *et al.*, 1969). An analysis of these waves indicates that they propagate in the neutral atmosphere. The waves are most prevalent at the higher latitudes near the auroral zone (the orbital inclination of the satellite is  $65^\circ$ ) and were observed most frequently in the late evening and early morning hours, but they were not limited to those latitudes and times. The apparent vertical half-wavelengths of the waves increase with altitude from 1 km at 286-km altitude to 70 km at 510-km altitude; their half-amplitudes in density range from the limit of detectability to a maximum of about 50% of the mean density. It appears that some of the observed wavelengths are integrally related, indicating the existence of "fundamental" wavelengths and of second, third, and fourth harmonics.

These waves have been interpreted as free internal gravity waves propagating predominantly from north to south or from south to north, with maximum horizontal wavelengths between 130 and 520 km. The altitude dependence of the apparent vertical half-wavelengths results from the satellite moving with varying vertical velocity through a slowly propagating wave pattern with nearly vertical phase planes. It is tempting to visualize these waves as part of the mechanism by which energy deposited in the auroral zones is conveyed to lower latitudes (see Section 8). In the densities derived from satellite drag, these waves are entirely smoothed out; their existence, however, must be kept in mind when comparisons are made between densities from satellite drag and densities obtained from high-resolution gauges.

#### 14. COMPARISON WITH OBSERVATIONS; DRAG COEFFICIENT

In Figures 13, 14, and 15, we have compared densities derived from the drag of several artificial satellites with those predicted by the present models.

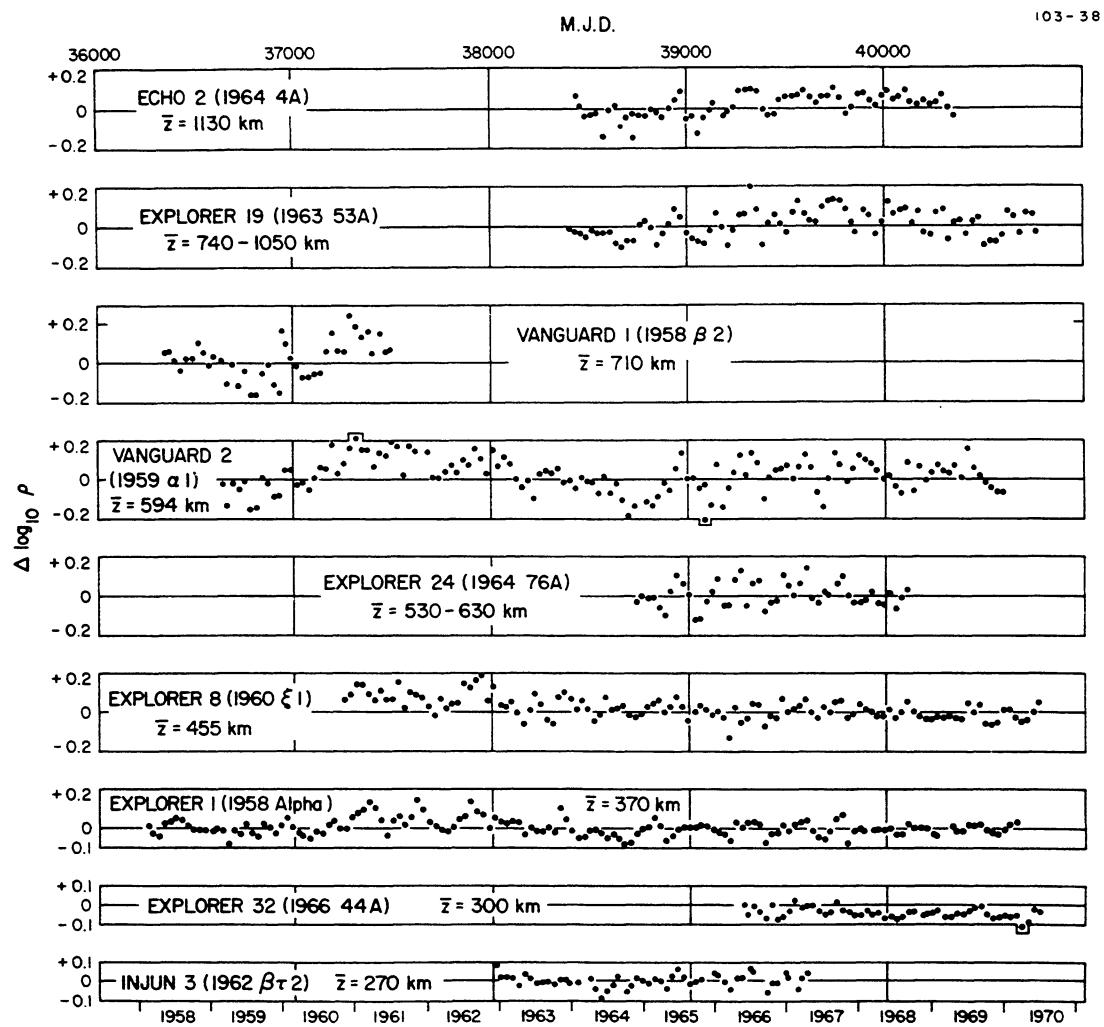

Figure 13. Thirty-day means of density residuals from the present models for nine satellites covering a wide range of heights.  $\bar{z}$  is the average effective height of the satellite (see text). The 12 years in the diagram cover a full sunspot cycle. The purpose of the figure is to show how effectively the models account for the density variation with height and with solar activity. M. J. D. is the Modified Julian Day (J. D. minus 2 400 000.5).

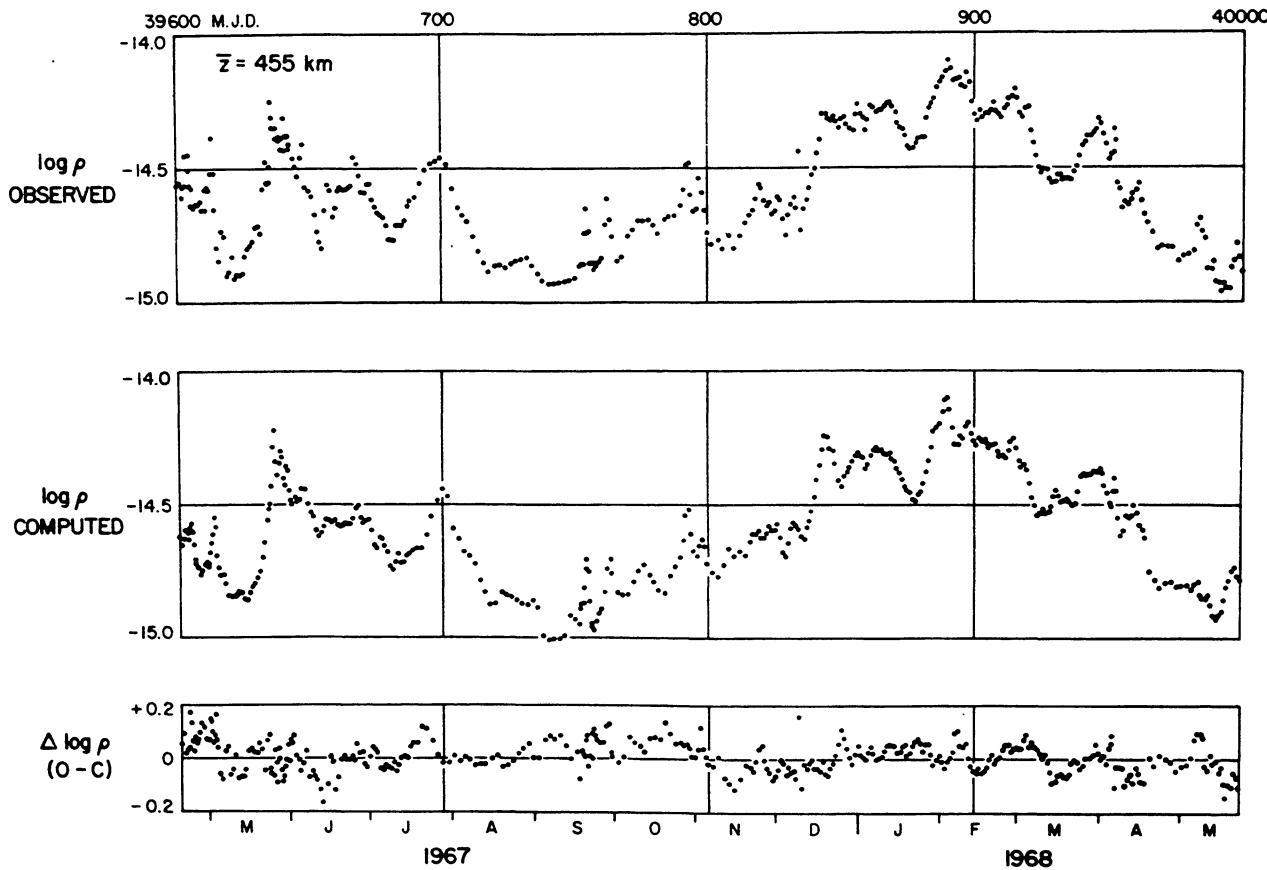

Figure 14. Observed and computed densities for Satellite 1960  $\xi$  1 (Explorer 8) during 1967 and 1968. The observed densities (top) were derived from drag analysis; the middle strip shows densities computed from the present models; the difference (O-C) is plotted at the bottom. The purpose of this figure is to show how effectively the models account for the diurnal variation (slow, 230-day oscillation) and the 27-day fluctuations in apparent solar activity.  
M. J. D. is the Modified Julian Day (J. D. minus 2 400 000.5).

In Figure 13, intended to show at a glance how closely the model represents the large, slow variations with the 11-year solar cycle, we have plotted 30-day means of the density residuals for nine satellites with effective heights ranging from 270 to 1130 km. The data cover the 12-year interval from 1958 to 1970, i.e., an entire solar cycle.

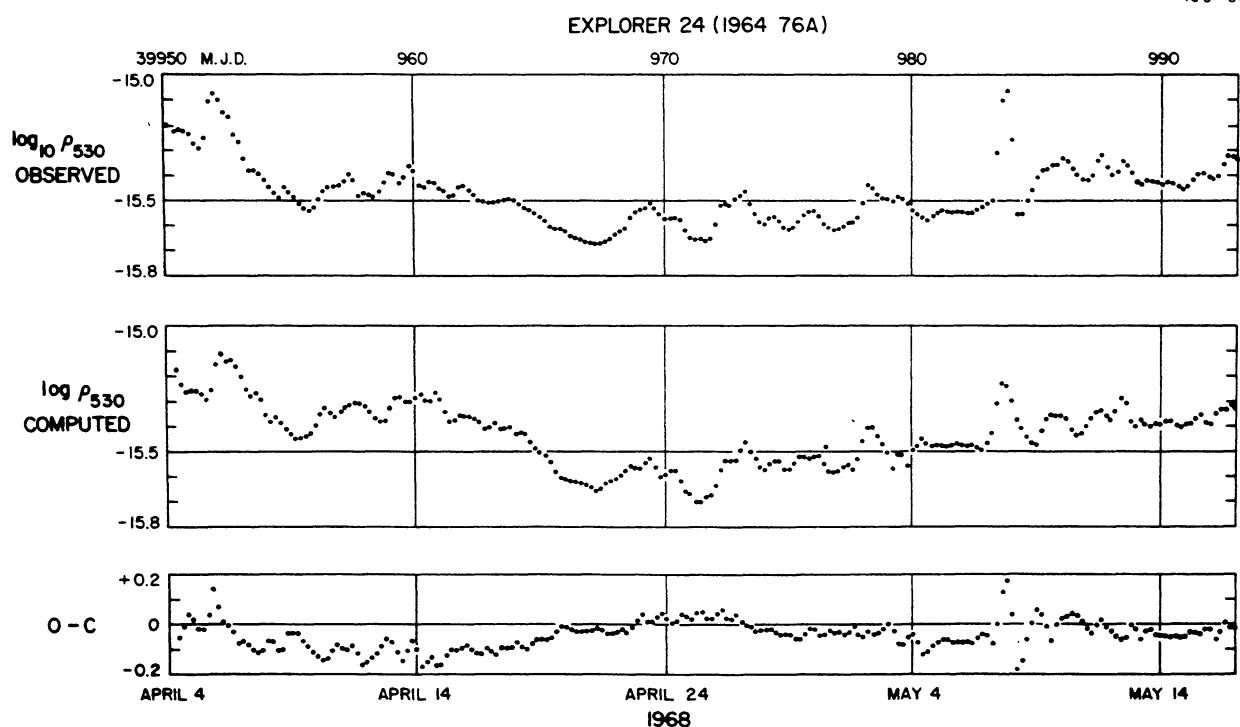

Figure 15. Observed and computed densities, reduced to a standard height of 530 km, for Satellite 1964 76A (Explorer 24) during 46 days in April and May 1968. The observed densities were derived from drag analysis by use of positions from precision-measured photographs taken with the Baker-Nunn cameras; the middle strip shows densities computed with the present models; the difference (O-C) is plotted at the bottom. The purpose of this figure is to show how effectively the models account for the geomagnetic effect. All the fluctuations with a characteristic time of 1 to 5 days are caused by the geomagnetic effect and are superimposed on a slower oscillation caused by the 27-day variation in solar activity. M. J. D. is the Modified Julian Day (J. D. minus 2 400 000.5).

Figure 14 compares observed and computed densities on a shorter time scale. The observed data are the densities derived from the drag analysis of field-reduced positions obtained from photographs taken by the Baker-Nunn cameras for Satellite 1960 §1 (Explorer 8). These positions have an accuracy of about 2 arcmin and permit a resolution of 1 to 2 days, except around

magnetic storms, where a resolution of 0.5 days or higher might be achieved. In the computed densities, a variable smoothing factor has been used in the geomagnetic effect to match the actual resolution. The large, slow fluctuation in the densities, with a period of 230 days, is caused by the diurnal variation (see also Figures 5 and 6); the superimposed fluctuations are caused by the 27-day variations in the apparent solar activity, by the variations in latitude of the satellite perigee, and by magnetic storms (such as the sharp peak in May 1967, near the beginning of the diagram, and the two peaks in the second half of September 1967). The entire time interval covered by the diagram was one of lively 27-day variations connected with solar rotation.

Figure 15 shows observed and computed densities on an even shorter time scale. The observed data are, this time, densities derived from the drag analysis of precise positions obtained, by photoreduction of Baker-Nunn films, for the 12-foot balloon satellite Explorer 24 (1964 76A). The accuracy of these positions is of the order of 3 arcsec. This accuracy, combined with the high drag of the satellite, allowed a resolution of 0.2 days throughout the interval covered by the diagram. Here the slow background variation is caused by the 27-day oscillations, while all the numerous irregular fluctuations seen throughout the diagram are caused by the geomagnetic effect.

The height  $\bar{z}$  marked on each diagram is the average effective height to which the data refer. The effective height, variable from revolution to revolution, is the weighted mean of the heights above the geoid in the course of one revolution, with the drag taken as the weight. For moderate and high orbital eccentricities, this "effective" height is approximately half a density-scale height higher than the perigee height; for zero eccentricity, of course, it is close to the perigee height itself.

In the computation of densities from satellite drag, we have used a drag coefficient  $C_D$  variable according to theory (Cook, 1965), in which the numerical parameters in the accommodation coefficient have been selected in such a way as to give  $C_D = 2.2$  at heights between 200 and 400 km. The

actual value of the drag coefficient was computed point by point along the satellite orbit by means of the present atmospheric models, which are also used in the numerical-integration process leading from the observed drag to the corresponding density.

## 15. NUMERICAL EXAMPLES

Suppose we want to find the atmospheric density given by the models above a point with the following geographic coordinates:

longitude =  $120^{\circ}$ W of Greenwich, latitude =  $+45^{\circ}$  ,

on January 20, 1969, at  $19^{h}11^{m}$  U.T. =  $11^{h}0^{m}$  L.S.T., for three heights:  $z = 350, 140,$  and  $800$  km.

We shall first compute  $T_c$  from equation (14). For that purpose, we need the smoothed solar flux  $\bar{F}_{10.7}$  for that date and the actual flux  $F_{10.7}$  on the day before (to account for the lag of  $1^d 0^h$ ). Consulting solar records, we find the following:  $\bar{F}_{10.7} = 155$ ,  $F_{10.7} = 136$ , so  $T_c = 856.5$ . This is the minimum exospheric temperature anywhere on the globe at the desired instant, for quiet geomagnetic conditions ( $K_p = 0$ ).

Next we shall use equation (16) or Table 1 to compute the exospheric temperature  $T_\ell$ . The declination of the sun on January 20.8 was  $-20.0^{\circ}$ . For  $\phi = +45^{\circ}$  and L.S.T. =  $11^{h}0^{m}$ , Table 1 gives  $T_\ell/T_c = 1.158$ , so we obtain  $T_\ell = 991.8$ .

We must now add the effects of the semiannual variation and of geomagnetic heating. Let us start with the geomagnetic effect, because it involves a temperature change. We must first look up the value of  $K_p$  at a time  $6.7$  hours before the desired date; from geomagnetic records we find  $K_p = 2_0$ . If we use equation (18), we find (Table 2a)  $\Delta T = 56^{\circ}$ ; adding this to  $T_\ell$ , we find  $T_\infty = 1048^{\circ}$ . If we look up  $\log \rho$  in the basic tables for  $T_\infty = 1048^{\circ}$  and  $z = 350$  km, we find, by interpolation, the value  $-13.976$  ( $\text{g cm}^{-3}$ ). To this value we must still add a correction for the semiannual variation. From Table 3 we obtain  $f(z) = 0.207$ ,  $g(t) = -0.183$ , so  $\Delta \log \rho = f(z) g(t) = -0.038$ . Adding, we find  $\log \rho = -14.014$ . According to Table 5, seasonal-latitudinal

variations are negligible at 350 km, and since at this height the basic tables show helium to be a negligible constituent, we have no further corrections to make to the value of  $\log \rho$  we just found. If we had decided to use the hybrid equations (20) to compute the geomagnetic effect, we would have had to add to  $T_f$ , according to Table 2b, a correction  $\Delta T = +28^\circ$  and to  $\log \rho$  a correction  $+0.024$ . This would have led to  $T_\infty = 1020^\circ$  and a final  $\log \rho = -14.028$ .

For  $z = 140$  km, we can no longer neglect the seasonal-latitudinal variations, and we must use equations (20) to compute the geomagnetic effect. We shall thus have  $T_\infty = 1020^\circ$ , as in the previous example when we used equations (20); for this temperature and  $z = 140$  km, the basic tables give  $\log \rho = -11.413$ . With a correction  $\Delta \log \rho = +0.024$  for the geomagnetic effect, this becomes  $\log \rho = -11.389$ . For the seasonal-latitudinal variation, Table 4 gives  $S = 0.027$ ,  $P = +0.882$ ,  $\sin^2 \phi = 0.500$ , from which we obtain  $\Delta \log \rho = SP \sin^2 \phi = +0.012$ . So the final density is  $\log \rho = -11.377$ .

For  $z = 800$  km, we can again neglect the seasonal-latitudinal variation of the lower thermosphere, but we find that helium is not negligible, so that a correction to the helium concentration must be computed from equation (25) or found in Table 5. Let us use equation (18) for the geomagnetic effect. We shall then have  $T_\infty = 1048^\circ$ ; for this temperature and  $z = 800$  km, the basic tables give  $\log \rho = -16.795$ . With the correction  $\Delta \log \rho = -0.038$  for the semiannual variation, we obtain  $\log \rho = -16.833$ , i.e.,  $\rho = 1.60 \times 10^{-17}$ . From the basic tables, we derive, for  $T_\infty = 1048^\circ$ ,  $\log n_0(\text{He}) = 5.958$ ; to this value we must apply, according to Table 5, a correction  $\Delta \log n(\text{He}) = +0.243$ . Converting to natural values:  $n_0(\text{He}) = 9.08 \times 10^5$ ,  $n(\text{He}) = n_0(\text{He}) + \Delta n(\text{He}) = 15.89 \times 10^5$ , whence  $\Delta n = 6.81 \times 10^5$ . The correction to the total density can be computed from  $\Delta \rho = [M(\text{He})/A] \Delta n(\text{He})$ , where  $M(\text{He})$  is the atomic mass of helium, 4.0026, and  $A$  is Avogadro's number,  $6.02257 \times 10^{23}$ . We obtain  $\Delta \rho = 0.453 \times 10^{-17}$ ; the final density is  $\rho = 1.60 \times 10^{-17} + 0.45 \times 10^{-17} = 2.05 \times 10^{-17}$ .

						27	-0.107

Table 4. Tables for the seasonal-latitudinal density variation  
 $\Delta \log_{10} \rho = SP \sin^2 \phi$ .

a) Table of the maximum half-range  $S = 0.014(z - 90) \exp [-0.0013(z - 90)^2]$

$z$ (km)	$S$	$z$ (km)	$S$	$z$ (km)	$S$
90	0.000	120	0.130	150	0.008
95	0.068	125	0.100	155	0.004
100	0.123	130	0.070	160	0.002
105	0.157	135	0.045	165	0.001
110	0.166	140	0.027	170	0.000
115	0.155	145	0.015		

b) Table of the phase  $P = \sin(2\pi\Phi + 1.72)^*$

Day	P	Day	P	Day	P	Day	P
Jan. 1	$\pm 0.989$	Apr. 1	$\mp 0.129$	June 30	$\mp 0.994$	Sept. 28	$\pm 0.086$
11	$\pm 0.948$	11	$\mp 0.297$	July 10	$\mp 0.961$	Oct. 8	$\pm 0.255$
21	$\pm 0.880$	21	$\mp 0.456$	20	$\mp 0.900$	18	$\pm 0.417$
31	$\pm 0.786$	May 1	$\mp 0.602$	30	$\mp 0.812$	20	$\pm 0.567$
Feb. 10	$\pm 0.668$	11	$\mp 0.730$	Aug. 9	$\mp 0.699$	Nov. 7	$\pm 0.699$
20	$\pm 0.531$	21	$\mp 0.836$	19	$\mp 0.567$	17	$\pm 0.812$
Mar. 2	$\pm 0.378$	31	$\mp 0.918$	29	$\mp 0.417$	27	$\pm 0.900$
12	$\pm 0.214$	June 10	$\mp 0.972$	Sept. 8	$\mp 0.255$	Dec. 7	$\pm 0.961$
22	$\pm 0.043$	20	$\mp 0.998$	18	$\mp 0.086$	17	$\pm 0.994$
						27	$\pm 0.998$

\*Take the upper sign for the Northern Hemisphere, the lower for the Southern Hemisphere.

c) Table of  $\sin^2 \phi$

$\phi$	$\sin^2 \phi$	$\phi$	$\sin^2 \phi$	$\phi$	$\sin^2 \phi$
$0^\circ$	0.000	$30^\circ$	0.250	$60^\circ$	0.750
5	0.008	35	0.329	65	0.821
10	0.030	40	0.413	70	0.883
15	0.067	45	0.500	75	0.933
20	0.117	50	0.587	80	0.970
25	0.179	55	0.671	85	0.992
				90	1.000

Table 5. Seasonal-latitudinal variations of helium (correction to tabular helium concentrations  
 $\Delta \log_{10} n(\text{He})$  according to equation (25)).
