Received 1973 May 16

ABSTRACT

A photometric *UBV* study to $V = 17.2$ of the globular cluster NGC 4372 has revealed: (1) a color-magnitude diagram characteristic of very metal-poor clusters; (2) a large and variable absorption in front of the cluster; and (3) a distance modulus of 13.65 ± 0.20 . Attention is drawn to a relatively well populated group of stars lying above the horizontal branch in the color-magnitude diagram.

Subject headings: abundances, stellar — globular clusters — interstellar reddening

I. INTRODUCTION

In spite of the fact that the southern globular cluster NGC 4372 [$\alpha(1950) = 12^h23^m0$, $\delta(1950) = -72^\circ24'$; $l^{\text{II}} = 301^\circ$, $b^{\text{II}} = -10^\circ$] has an unusually low degree of central concentration, which in general facilitates an observational study, no published color-magnitude (C-M) diagram is available for this cluster. In view of the importance of obtaining C-M diagrams for as many of the galactic globular clusters as possible with the ultimate aim of understanding the early evolution of the Galaxy, we obtained photoelectric *UBV* and photographic *B*, *V* photometry of NGC 4372 over a 3-year period when time was available from our metal-rich globular cluster observing program (Hartwick and Hesser 1972). To aid in the disentangling of the complex reddening in the region, additional photometric data for early-type field stars were obtained in the *uvby*- $H\beta$ system. This paper presents the results of these observations.

II. OBSERVATIONS

The photoelectric data obtained for NGC 4372 consist of a sequence of bright secondary standards set up around the cluster on several nights in 1969 and 1970 with the 41-cm and 91-cm telescopes on Cerro Tololo using standard single-channel refrigerated 1P21, *UBV* equipment. These bright stars are identified in figure 1 (plate 5), and their magnitudes, colors, and number of observations are listed in table 1. The standard stars used have been described elsewhere (Hartwick, Hesser, and McClure 1972; Hartwick and Hesser 1972). Median internal standard errors for those stars with multiple observations are: ± 0.007 mag in *V*, ± 0.004 mag in $(B - V)$, and ± 0.005 mag in $(U - B)$. In addition to the bright stars of table 1, a sequence of fainter stars was observed photoelectrically with the 91-cm and 152-cm telescopes. These stars are also identified in figure 1, and the photometric data are given in table 2.

TABLE 1
PHOTOELECTRIC OBSERVATIONS OF BRIGHT STARS NEAR NGC 4372

| Star | V | $B - V$ | $U - B$ | n |
|--------|-------|---------|---------|-----|
| A..... | 6.59 | 0.00 | -0.04 | 10 |
| B..... | 8.90 | 0.54 | +0.05 | 9 |
| C..... | 9.50 | 1.13 | +0.82 | 6 |
| D..... | 9.89 | 0.58 | +0.05 | 7 |
| E..... | 11.26 | 1.34 | +1.09 | 9 |
| F..... | 9.24 | 0.49 | 0.00 | 5 |
| G..... | 10.63 | 0.37 | +0.18 | 1 |
| H..... | 10.30 | 0.42 | +0.11 | 7 |
| I..... | 12.10 | 1.51 | ... | 1 |
| J..... | 12.01 | 0.87 | +0.36 | 8 |

Median internal standard errors for these observations are: ± 0.02 mag in V and $(B - V)$, and ± 0.03 mag in $(U - B)$.

Photographic plates of NGC 4372 both in $V(103aD + GG14)$ and $B(103aO + GG13)$ were obtained with the $f/7.5$ camera of the 152-cm telescope. Iris photometry of 338 stars was carried out on two plate pairs. The brighter stars in the inner region (rings 1 and 2 of fig. 2 [plate 6] were measured on a 15-min-exposure plate pair. A larger group of stars including fainter ones were then measured in rings 3 and 4 of figure 2 on a 30-min-exposure plate pair. It was found necessary to apply a small color equation to the raw colors of stars measured on the 15-min plate pair. No corrections were applied to the second group of measurements. The stars are identified in figure 2 and are listed in table 3 according to the ring number shown on the figure. Based on

previous work we estimate the median internal standard error of a single observation in table 3 to be ± 0.02 mag in V and ± 0.03 mag in $(B - V)$. As unraveling the complex differential reddening (§ III) will require higher precision than we feel can be obtained by classical photographic photometry (even of several plate pairs), the only advantage to be accrued from additional photographic photometry would be the removal of the occasional accidental errors that go undetected when only one plate pair is measured. The agreement from stars in common on the bright and faint plate pairs measured was good, and we have chosen to present data from only one plate pair until such time as it becomes clear that the cluster deserves to be studied with greater precision by other techniques.

III. RESULTS

The color-magnitude diagram for NGC 4372 is shown in figure 3, where we have plotted the photoelectric results from table 2 as plus signs, the photographic results

FIG. 3.—The color-magnitude diagram for NGC 4372. Plus signs represent the photoelectric observations of table 2; open circles, the 1000 and 2000 stars of table 3; filled circles, the 3000 and 4000 stars of table 3.

for rings 1 and 2 of figure 2 as open circles, and the results for rings 3 and 4 as closed circles. In spite of the large scatter, the diagram shows a relatively steep giant branch and a blue horizontal branch, which are both characteristics of a metal-poor globular cluster.

Before comparing figure 3 with the C-M diagrams of other globular clusters, we shall estimate the reddening of NGC 4372. Figure 4 shows the two-color diagram for the stars in table 2 after correcting for a reddening of $E(B - V) = 0.42$ – 0.48 . The five reddest stars in figure 4 have had their reddening removed following the procedure of Hartwick and McClure (1972), which allows for the change in slope of the reddening trajectory as a function of intrinsic color. It is apparent from figure 4 that NGC 4372 is differentially reddened by approximately 0.06 mag. This result would account for part of the large scatter that we noted previously in figure 3. We attempted to map the differential reddening by plotting C-M diagrams for small regions of the cluster separately and from star counts. No systematic trends were obvious, so we conclude that the absorption is very patchy over the area studied.

As shown by Crawford and Barnes (1969), $uvby$ - $H\beta$ photometry (Strömgren 1966) of field B, A, and F stars can provide reliable reddening estimates for cluster fields. In 1972 we observed 32 stars from the HD catalog with the 61-cm Lowell-Tololo telescope equipped with a standard 1P21 photometer and CT10 filter set number 3. Five nights out of a much more extensive program were used to obtain the data for NGC 4372, and mean extinction and transformation coefficients determined from many nights were used for the reductions. The results are presented in table 4; the median internal standard errors of an individual measurement entering into the means, as determined from those stars with multiple observations, are 0.010, 0.004, 0.008, 0.012, and 0.010 mag for y , $b - y$, m_1 , c_1 , and β , respectively. The y -magnitudes of table 4 were obtained by linearly transforming to the V -magnitude of the UBV system. Reddening was determined individually using the preliminary relations of Crawford (1970). Similarly, the preliminary absolute-magnitude calibrations (Crawford 1972) were applied wherever possible, and allowances for evolutionary

FIG. 5.—A plot of reddening against distance derived from *uvby*- $H\beta$ photometry (table 4) for early-type field stars in the vicinity of NGC 4372. Beyond 250 pc, a leveling off and a large non-uniformity of the reddening are apparent.

effects in the A and F stars were included. Adopting $A_V/E(B - V) = 3.2$, the distances were estimated and the resultant plot of $E(B - V)$ versus distance is shown in figure 5. If, following the discussion of Arp (1965), an absorption layer thickness of 100 pc is assumed, the line of sight to NGC 4372 intersects the layer at a distance of 570 pc, well beyond the point (250 pc) where a leveling off of the reddening versus distance relation is evident in figure 4. The data of figure 4 and table 5 clearly demonstrate the nonuniform nature of the reddening in the vicinity of NGC 4372. From the 18 stars with $r \geq 250$ pc, an average reddening of 0.26 mag is found, but a scatter of 0.10 mag in the individual values is present. Although the UBV data indicate that the more immediate vicinity of the cluster (not sampled in the $uvby$ - $H\beta$ photometry due to the lack of bright, early-type stars) suffers from reddening that is slightly higher than average for this field, the $uvby$ - $H\beta$ results seem to be consistent with the UBV analysis presented above.

As a final check on our reddening determination, as well as to enable an estimate of the distance modulus to be made, we superposed our figure 3 on those of two well-studied clusters with similar C-M diagrams. As a result of the comparison with M92 (Sandage and Walker 1966; Sandage 1970) we find $E(B - V)_{4372} = 0.45$ and $(m - M)_{0,4372} = 13.5$ assuming that $E(B - V)_{M92} = 0.02$ and $(m - M)_{0,M92} = 14.56$ (Sandage 1970). Using M2 (Arp 1955) as the standard cluster,¹ we find $E(B - V)_{4372} = 0.40$ and $(m - M)_{0,4372} = 13.8$ with $E(B - V)_{M2} = 0.05$ and $(m - M)_{0,M2} = 15.6$ from Arp (1955). We should emphasize that the features of figure 3 are very similar to those in the C-M diagrams for both M92 and M2.

Many years ago Deutsch (Kinman 1959) classified several globular clusters into three groups based on the strength of the metal lines in the spectra of individual giant-star members. On this system M92 was classified as type C (extremely poor) and M2 as type B (moderately metal poor). Kinman (1959) applied Deutsch's scheme to several southern globular clusters, among them NGC 4372, which he classified as type B. The results of this paper are consistent with Kinman's classification.

Before concluding, we wish to draw attention to a possible group of stars at $V \simeq 14.3$, $B - V \simeq 0.92$. These stars occupy the same region of the C-M diagram as certain stars isolated by Strom *et al.* (1970) and by Zinn, Newell, and Gibson (1972) in a number of other globular clusters. Should further study show that these stars are radial-velocity members, then NGC 4372 would be unusual in having so many of these stars.

IV. SUMMARY

From our photometric investigation of NGC 4372 in the UBV and $uvby$ - $H\beta$ systems, we conclude that: (1) The C-M diagram of the cluster is characteristic of very metal-poor clusters, a conclusion consistent with Kinman's (1959) spectroscopic classification. (2) The cluster is heavily reddened, and this reddening is patchy over an $8'$ region centered on the cluster. We find $E(B - V) = 0.42$ - 0.48 . (3) The distance modulus of NGC 4372 is approximately $(m - M) = 13.65 \pm 0.20$. (4) A group of stars at $V \simeq 14.3$ and $(B - V) \simeq 0.92$ is apparently analogous to the distinct group of stars isolated in other clusters by Zinn *et al.* (1972). If future radial-velocity measurements show that these stars are members, then NGC 4372 would appear to be distinguished in having a populous group of supra-horizontal-branch stars.

We wish to thank Srta. Laura Vega and Mrs. Jeannette Barnes for their invaluable aid in the data reductions, and one of us (F. D. A. H.) wishes to acknowledge financial support from the National Research Council of Canada and the University of Victoria.

¹ The transformation from the m_{pg} , m_{pv} system to the B , V system for M2 was achieved using the relation given by Arp and Melbourne (1959).
