# REDSHIFTS OF 165 ABELL AND SOUTHERN RICH CLUSTERS OF GALAXIES 

H. Quintana ${ }^{1}$ and A. Ramírez ${ }^{2}$<br>Astrophysics Group, Physics Faculty, Universidad Católica de Chile, Casilla 104, Santiago 22, Chile; hquintana@astro.puc.cl Received 1994 April 4; accepted 1994 July 8

#### Abstract

We present spectroscopic observations and accurate positions for 286 galaxies in clusters taken over several observing sessions, mostly with the DuPont telescope at Las Campanas Observatory. We derive 165 redshifts of rich clusters of which 130 are apparently new values. Redshifts encompass a wide range out to $z=0.27$.

Subject headings: galaxies: clusters: general —galaxies: distances and redshifts

## 1. INTRODUCTION

Recent years have witnessed a rapid increase in the interest in southern clusters of galaxies. The availability of large telescopes and the completion of the southern extension of the Abell catalog (Abell, Corwin, \& Olowin 1989, hereafter ACO), giving a convenient, if not totally complete, database and a much needed set of standard names, have meant that optical data on southern clusters can be more readily and systematically obtained and compared. Redshifts of clusters are basic data useful in many types of studies, and for southern clusters they are sparse. The largest compilation is by Struble \& Rood (1991, hereafter SR91). Also, the galaxy catalog by Fairall \& Jones ( 1991 ) is very useful, and we use it extensively.

As backups or by-products of several observational programs carried out from telescopes in Chile, we have obtained a number of spectroscopic observations of one or more galaxies in a number of Abell and miscellaneous northern and southern clusters. Most of these are new galaxy redshifts, which we present here with details of the observational and reduction procedures. When velocities are available we compare our results to previous redshifts measurements, as indicated below. As can be expected, in a few cases we find redshifts discordant with those in the literature and indicate, if possible, sources of discrepancies. We point out that redshifts in clusters in the general direction of the Shapley 8 supercluster (approximate R.A. $=$ $13^{\mathrm{h}} 30^{\mathrm{m}}$ and Decl. $=-31^{\circ}$ ) are being reported elsewhere (Quintana et al. 1994b).

Most clusters observed are Abell clusters of Bautz-Morgan types I, I-II, and II, where these types have been taken from ACO. A small number of clusters come from the Quintana \& White (1990) catalog ( hereafter QW90), for which we use QW numbers. In that list we gave preliminary redshifts now superseded by the present values. Finally, a few clusters are from the Zwicky catalog, observed because either they were detected as X-ray sources (by the Einstein Observatory) or because they

[^0]contain central dumbbell galaxies. In fact, many Abell clusters were also observed because they have central dumbbells.

## 2. SPECTROSCOPIC OBSERVATIONS

The spectroscopic observations were carried out using several telescopes and detectors, over a period of several years. In most clusters we observed the obvious brightest cluster member (BCM, for short), when its appearance showed it to be a cD , dumbbell $\mathrm{BCM}, \mathrm{gE}$, or D galaxy, normally close to the cluster center or at a high galaxy density enhancement in the cluster. If two such galaxies were present, we measured both, observing time and conditions permitting. Most of the observations reported here used either the intensified Reticon or the intensified "2D-FRUTTI" detector at Las Campanas Observatory (LCO). Both are photon-counting devices so that the observer can display the spectra as the observation proceeds and estimate a rough velocity, deciding to observe more galaxies if different redshifts were obtained in any cluster. Thus, occasionally three or more velocities were observed in a cluster.

The telescopes, dates, instrumental setups, and observational parameters are shown in Table 1, which identifies the several observing sessions, as follows.

### 2.1. Group A, Session 1: LCO Modular Spectrograph

The Dupont 2.5 m telescope at LCO was used on two nights in 1991 February, with the Modular spectrograph attached. A 600 -line grating, blazed at $5000 \AA$, gave of dispersion of $2.4 \AA$ $\mathrm{mm}^{-1}$ covering the spectral range $4400-6850 \AA$. The detector was a $1024 \times 1024$ thick $12 \mu \mathrm{~m}$ pixel CRAF CCD, giving a 2 pixel resolution of 3-4 At the center of the spectrum. A 185 $\mu \mathrm{m}$-wide slit, or $2^{\prime \prime}$ on the sky, was used for all the observations, providing a 6 pixel resolution along the slit and an approximate useable field of $10^{\prime}$. The dispersion axis, showing small distortions, was carefully aligned along the columns. However, on the CCD the slit shape showed a noticeable distortion due to the transfer lens. To correct for pixel-to-pixel sensitivity and large-scale detector and illumination variations we obtained flat fields off the dome and exposures of the twilight sky on both nights. To correct for the slit-image geometrical distortions, we also took long exposures of both helium and hollow cathode comparison lamps. To calibrate each exposure in wavelength we recorded comparison exposures

TABLE 1

with both lamps before and immediately after each object exposure. Below, we give the rotator angle of the slit, which in the DuPont telescope is measured from north to west (clockwise), with $90^{\circ}$ taken in the north-south orientation. The standard position angle is then equal to 270 minus the rotator angle.

To calibrate the zero point of the velocity scale and to secure suitable templates, a number of standard velocity stars were observed, of spectral types G8 to K2 (HD 55229, HD 55434, and HD 71370), as were a few nearby galaxies, particularly with known internal velocity dispersions (NGC 2217, NGC 2784, and NGC 2775). In order to calibrate the system response we also observed a few spectrophotometric standards (LTT 2415, LTT 2511, LTT 1788, LTT 3218, and L74546A). The observations were carried out under photometric conditions the first night. However, on the second night conditions deteriorated from clear skies at sunset to heavy clouds in the last hours of the night. We had a quarter moon in the first halves of both nights.

### 2.2. Group B, Sessions 2-8: LCO 2D-FRUTTI Detector

The 2D-FRUTTI detector (Shectman 1989) was used on the 2.5 m Dupont telescope, in all the sessions at LCO between 1985 and 1989. The Boller \& Chivens spectrograph was fitted with the same 600 line $/ 5000 \AA$ grating and the angle adjusted to give a spectral coverage between 3600 and $7000 \AA$, approximately, in all the runs but the first. The image size on the detector was chosen to be either 1520 or 3040 pixels along the dispersion axis and 256 or 128 pixels along the single slit direction, depending on the session (as indicated in Table 1), corresponding to a spectral resolution of 9 or $5 \AA$ and a spatial resolution of $5^{\prime \prime}$ along the slit, which had a useful projected length on the sky between 4.5 and 9 ! in the first of these sessions, a grating with 1200 lines blazed at $5000 \AA$ was used, providing a
wavelength coverage from 3870 to $5960 \AA$ and a resolution of $5 \AA$ on the 1520 pixel-long image.

Calibration of the sensitivity variations of the 2D-FRUTTI was achieved by exposures of a low-intensity quartz lamp off the inside of the dome taken every other day, using several grating angles to secure a fairly even illumination of the whole detector (up to 500-1000 counts pixel ${ }^{-1}$ ). Similarly, to map the distortions along the dispersion direction, exposures of the same lamp, with several grating angles, were taken through a hole pattern of the slit. On some nights, when there was a fair amount of moon, we also took spectra of stars, placing them at regular intervals along the slit. In this way it was confirmed that no change in the spectra shape, along the dispersion, occurred between different grating angles. To correct for any illumination effects due to slit imperfections, field vignetting, or other causes, exposures of the twilight sky were taken every night.

Objects were observed until the display of their spectrum showed signs of several absorption or, occasionally, emission lines. Usually, the H and K lines and the G band appear first on the early-type galaxies. If the observed galaxy appeared on the finding chart to be clearly a BCM and a rough screen estimate of the redshift agreed with the range corresponding to the distance class and cluster appearance, no other galaxy was observed in the Abell clusters. When a second BCM was present, particularly at a separate density enhancement, then a second spectra was normally taken. In a few cases, these were clearly discrepant, which led us to observe further galaxies. Typical exposures were from 10 to 60 minutes. Most clusters observed have Abell distance classes 5 and 6, so long exposures are needed to get an adequate signal-to-noise spectrum. Then the above procedure was not always feasible, because we run out of time, or because of clouds. Helium and argon comparison lamp exposures were taken immediately before and after an object exposure, unless we observed other galaxies in the same cluster, in which case comparison lamps were taken be-
fore and after the first and last exposures. Between both no more than 2 hr elapsed. To calibrate the zero point of the velocity scale and secure templates, a number of standard velocity stars were observed, of spectra types G8 to K2, as well as a number of nearby galaxies with well-known internal velocity dispersions, selected from the catalog of Whitmore, McElroy, \& Tonry (1985).

### 2.3. Group C, Sessions 9-12: LCO Shectograph Detector

These sessions were mainly devoted to obtaining galaxy velocities in a few rich clusters in an effort to determine cluster dispersions. However, at times we observed a number of additional galaxies. The Dupont telescope was used with the Boller \& Chivens spectrograph fitted with the Reticon spectrometer two-channel detector (Shectman 1981). The same $600-l i n e$ grating as above was used in the spectrograph, giving a similar spectral range and resolution in the 3744 pixel-long channels. Further details of the observational technique and instrumental setup are given in Quintana \& Ramírez (1990, hereafter QR90). A few of these new redshifts were quoted in QW90, without details of observations and galaxy identifications, which we give here, together with a new reduction and crosscorrelation measurement of the data.

### 2.4. Group D, Sessions 13 and 14: CTIO 4 m Telescope

The 4 m telescope at CTIO was used with the SIT Vidicon detector on the sessions indicated. The main objects observed were central dumbbell galaxies in clusters. Some of these velocities provide new cluster redshifts and are included here for completeness. The Boller \& Chivens spectrograph was fitted with the KPGL No. 1 grating, giving a wavelength coverage between 3700 and $5540 \AA$. The slit was set at $225 \mu \mathrm{~m}$. The image sizes were 1024 and 1300 pixels along the dispersion axis, and 140 or 250 pixels across, giving a resolution of approximately $3.5-3 \AA$ in wavelength and a projected spatial resolution of 1.12 pixel $^{-1}$, along the slit. A white spot was used to obtain flat fields to correct for detector small-scale variations. Exposures taken through a decker with a hole pattern served to correct for S-distortions in the image tube. Long zenith exposures were used to correct for distortions along the slit. Helium-argon lamps were taken before and after each exposure at the position angle adjusted to record both dumbbell components. Session 14 was heavily affected by clouds, and a further session in April 1983 with this instrument was completely wiped by clouds. At the CTIO 4 m telescope, the rotator angle of the slit directly indicates the position angle, from $0^{\circ}$ in the north-south orientation, measured from north to east (counterclockwise).

## 3. POSITIONS OF OBSERVED GALAXIES

Some of the positions given in the literature for Abell clusters (north and, to a lesser extent, in the south) can differ somewhat from the positions of the central galaxies or are rough averages of the general cluster regions. For identification purposes we provide for each of the observed galaxies their 1950.0 epoch coordinates. When available, these positions were taken from the literature as indicated in the Table below. A number of them were measured from the SRC/ESO (B or J) or PSS glass
copies, using the Optronics machine at ESO, Garching, with reference to some 20-30 SAO or Perth astrometric standards. Many of the values from the literature were measured with this same machine. For a large majority, positions were measured from PSS prints or ESO/SRC J or R films, with a simple digitized $x-y$ light table at Santiago, with reference to 12-15 SAO stars in the vicinity of each cluster. In the first case the external error is estimated to be $1^{\prime \prime}-2^{\prime \prime}$, while in later cases this value is estimated at $6^{\prime \prime}-10^{\prime \prime}$. In Table 3 we indicate the source of the given positions. Some of these are from the ESO/Uppsala catalog (Lauberts 1982) or are Parkes radio source positions.

## 4. REDUCTION PROCEDURES AND VELOCITY MEASUREMENTS

All reductions were done within the IRAF ${ }^{3}$ environment, ver. 2.9 and 2.10.2. Some preliminary work has been done using other reduction packages, but for homogeneity all the data was later reduced again with IRAF.

### 4.1. Modular Spectrograph Data

The CCD image has little distortions, with the spectra running along the columns. The spectra was extracted using the task APSUM, fixing the apertures to be $2-3$ pixels by selecting the peaks of the fiber images from a cut across the dispersion axis. Object, sky, and comparison spectra were extracted following third-order Legendre functions. Spline-3, order-7 functions were used for wavelength calibrations, resulting in rms errors of $0.2 \AA$. We checked the calibration with the $5577.35 \AA$ night-sky line, which showed errors no larger than $0.5 \AA$.

### 4.2. 2D-FRUTTI Spectra

Due to the nature of the 2D-FRUTTI system we have the typical S-shaped distortions inherent to this instrument. Therefore the first step was to transform our curved spectra to straight via the transform algorithm in the LONGSLIT package, using the multihole frames and a zenith long comparison lamp exposure. The response along the slit was normalized using the frames of sky taken at twilight. Sky subtraction was done extracting two parallel 8 pixel apertures on each side of the galaxy spectrum, all three following an order-3, spline-3 curve, to catch discontinuities that are caused by the microchannel and image intensifiers of the 2D-FRUTTI. The mode of both sky spectra was retained to check wavelength calibration from the positions of sky lines. Comparison spectra were extracted following curves with the same parameters as object spectra. The wavelength solutions for $24-30$ points using a fourth- or fifth-order Legendre typically yielded residual values less than 0.3 rms Å.

### 4.3. Intensified Reticon (Shectograph) Data

The two channels were switched on and off between galaxy (object + sky) and sky several times during the exposures. Sky subtraction is straightforward. Together with wavelength cali-

[^1]bration procedures, comparison with other data is described by QR90.

### 4.4. SIT Vidicon Data

The image has similar distortions, but much milder, than the 2D-FRUTTI two-dimensional spectra. Thus the same methods were used to extract the one-dimensional spectra from the image and perform sky substraction and wavelength calibration.

### 4.5. Velocity Measurements

For most of the data (excepting the older Vidicon spectra for which no cross-correlation method was applied) three different methods were used to measure the redshift of the objects. The first method applied was a line-by-line Gaussian fitting to the strongest lines, such as the H and K Ca II bands, G band, Mg I, and/or Balmer jump. For normal early-type spectra we were able to use two different cross-correlation algorithms now currently supported inside of IRAF (RV and RVSAO), with correlation peak fitting done by a parabolic adjustment. However, for non-early-type spectra (i.e., emission lines, $\mathrm{E}+\mathrm{A}$, etc.) we resorted to the line-by-line Gaussian fit. Additionally, when a low Tonry \& Davis (1979) $R$-value ( $R \leq 4$ ) was obtained, this would indicate that the cross-correlation result was acceptable only if it agreed with the Gaussian line fitting. If the fitting method showed credible lines and the $R$ number was particularly low or, on occassion, extremely poor (i.e., below 2 or 2.5 ), we kept those values derived from at least five lines. However, in Table 3 we quote all $R$-values.

To apply the correlation algorithms, spectra were contin-uum-subtracted and filtered with a ramp function in Fourier space, to remove high-frequency noise and low-frequency trends that persisted after the continuum subtraction. The Shectograph data were rebinned in log-linear scale with resolution $1.4 \AA$ pixel $^{-1}$, the 2D-FRUTTI spectra had a resolution of $2 \AA$ pixel $^{-1}$ (with the exception of session 8 which had $2.4 \AA$ pixel ${ }^{-1}$ ), and the corresponding value for the Modular data was $2.4 \AA \mathrm{pixel}^{-1}$. For object and template Shectograph spectra, initial and ending wavelengths were 3510 and $6800 \AA$, respectively. For the 2D-FRUTTI corresponding values were 3890 and $5900 \AA$, while for the Modular they were 4000 and $6850 \AA$, respectively. As templates, we used stars and galaxies which had high signal-to-noise ratios (S/N). For the Shectograph data, we used the spectra of HD 22663 and HD 23319, of types K0 and K2, while for the 2D-FRUTTI data we used spectra of 21 stars of types K0, K2, and G5. The template stars and galaxies used for the Modular data included HD 55229, HD 55434, and HD 71370 and NGC 2217, NGC 2775, and NGC 2784.

Similarly, spectra of galaxies NGC 1700, NGC 596, and NGC 1426 and 13 galaxies of types E0, E2, E4, E6, SB0 nuclei, and S0 were used as templates. All templates were correlated between them and were retained only if consistent solutions were found. Also, a synthetic spectrum, constructed from the library of stellar spectra of Jacoby, Hunter, \& Christian (1984), was used (details in Quintana, Ramírez, \& Way 1994c, hereafter QRW94). Different combinations of radial velocity templates served to derive Shectograph, 2D-FRUTTI,
and Modular velocities. Cross-correlation of the Shectograph data was performed with six templates, retaining the velocity produced by the correlation with the highest $R$-value if the velocities from all templates were consistent, had dispersions lower than individual errors, and agreed with the traditional line-fitting procedure, done previously. If there was no complete consistency, usually for $R \leq 4$ values, the cross-correlation procedures were performed interactively, searching for a peak at the position suggested by the line-fitting value. When no clear peak was present (very low values of $R$ ), the original line-fitting velocity was adopted. For the 2D-FRUTTI and Modular data we used all available templates running the XCSAO program in batch mode. If most templates ( 30 or more) gave consistent results, in the sense described, we adopted as final velocities the mean of the three values with highest $R$ numbers. Otherwise, the interactive procedure was followed and we adopted the velocity corresponding to the highest $R$-value.

A detailed comparison of both cross-correlation and linefitting procedures, using more than 400 velocities with $R>5$ values, showed consistent results between all methods. However, the velocity values of both correlations have a mutual dispersion which is smaller by a factor of 2 than the dispersion of any of the correlation results with the line-fitting velocities (further details in QRW94). On this basis we decided to retain the velocities obtained from the XCSAO program within RVSAO, which allows greater flexibility in its use and is likely to be more widely used. These are the values given in Table 3.

We could check the accuracy of our results by comparing the derived velocities with those known velocities for the template galaxies and dispersion calibrators, as well as the velocities of the star templates. Additionally, there is a large number of observed galaxies in some clusters that have numerous published velocities. These comparisons are presented in the papers quoted above (QRW94, QR90, Quintana et al. 1994b), and they will not be repeated here. Overall, they show that our errors are consistent with those published. Moreover, we discuss below our data consistency and give a comparison with values in the literature.

## 5. RESULTS

The heliocentric redshifts of 165 clusters are given in Table 2, where we show their positions from the ACO, QW90, or Zwicky catalogs, respectively, Bautz-Morgan types (BM), Abell richness (R) and distance (D) classes, the adopted $z$, and the number of measured velocities retained in its calculation $\left(N_{g}\right)$. Cluster numbers within parentheses are used to indicate redshift values for galaxy concentrations some distance from the main cluster density enhancement. Finally, in column (9), we give a comment concerning uncertainties of membership, either of our measured galaxies or the literature values. These are mostly taken from the compilation of SR91, which are corrected to the centroid of the Local Group. We also give other names given to these clusters and references for galaxy velocities, when these were different from ours. We have not included in Table 2 those clusters for which a sizeable number of galaxy velocities are known already, but we give in Table 3 below a few additional velocities from our data.

Rhee88 = Rhee \& Katgert 1988. Schneider83 = Schneider et al. 1983. Smith85 = Smith et al. 1985. SR = Struble \& Rood 1987 (SR1) or 1991 (SR2). VC88 = Valentijn \& Casertano 1988.

Velocities for the individual galaxies and details concerning each observation are given in Table 3. Here we include galaxies for a number of clusters with well-known redshifts, though some galaxies observed have no previous velocities measured. Columns (2), (3), and (4) show the 1950.0 epoch equatorial coordinates of each measured galaxy and a code ( P ) indicating their sources, as described in $\S 3$ and listed in the notes to this table. Usually, we give only one position for close dumbbells, identifying each component by its relative orientation. Columns (5), (6), and (7) show the independently measured heliocentric velocities of each galaxy, their errors, and TonryDavis $R$ numbers or, if an integer appears, number of lines measured (the latter for sessions 13 and 14). Uncertain values are preceded by a colon. An asterisk in front of a velocity indicates an entry from the literature, as emphasized by the entry "lit" in column (8). In columns (8), (9), and (10) we give information concerning the observations: our identification code for galaxies, session and telescope code S (according to Table 1), and exposure times $t$ in minutes. Finally, column (11) shows comments and slit rotator position $(r)$, as used in each telescope and described in $\S 2$. Rotator values correspond-
ing to the standard east-west orientation are not indicated (values $180^{\circ}$ at LCO 2.5 m and $90^{\circ}$ at CTIO 4 m ). The comment also may include other common names for clusters or galaxies, comments on the galaxy rank or position within the cluster, presence of emission lines, or other characteristics. Also, in brackets we note observing conditions, in particular moon phase, clouds, and seeing, with the following conventions: No comment is given if an observation was performed in dark and clear skies, with good seeing (between $1^{\prime \prime}-1 " 5$ ), taken as default condition. We indicate as excellent seeing below $1^{\prime \prime}$ (es), fair seeing $1^{\prime \prime} 5-2^{\prime \prime}$ ( fs ), bad seeing $2^{\prime \prime}-3^{\prime \prime}$ (bs), and very bad seeing worse than $3^{\prime \prime}$ (vbs). Presence of varying amounts of moonlight (m) and clouds (cld or cirrus) are marked. Comments for literature velocity lines indicate references listed in the notes ( some authors give velocities corrected for galactic rotation, as marked). We stress that we quote literature values if we think these are for the same galaxy (other velocities in the clusters are reflected in the redshifts of Table 2). However, it is not unusual that galaxy identifications are given without exact positions (or without their accuracies) or no finding charts instead. This leaves, at times, some uncer-

tainty on cross-identifications. Other notes point out special circumstances, galaxy configurations, or discrepancies.

A total of 330 independent velocities were obtained for 286 galaxies. We give two velocities for 22 galaxies, three for eight, and four for two. From these we can evaluate our internal consistency. If we disregard two very discrepant values ( of 950 km $\mathrm{s}^{-1}$ in A720 and $420 \mathrm{~km} \mathrm{~s}^{-1}$ in A883) we have a rms dispersion of $69 \mathrm{~km} \mathrm{~s}^{-1}$. This dispersion is similar to the mean of individual velocity errors. Therefore, in spite of different instruments, we feel that the common reduction and measurement procedures give satisfactory values.

The external comparison reflects the varying quality of literature redshifts. There are some large discrepancies, as noted in Table 3. Some of these discrepancies may just reflect very old (and/or weak) spectra ( such as some of the ESO/Uppsala values, which have a quoted error of $300 \mathrm{~km} \mathrm{~s}^{-1}$ or larger). If we restrict our comparison to data of similar quality, we have a total of 62 common velocities. From them we derive a mean difference of $10 \pm 211 \mathrm{~km} \mathrm{~s}^{-1}$. Though the scatter is larger than the internally deduced value, this result is consistent with expected errors and there is no zero-point shift of the velocity scale.

## 6. DISCUSSION

It has become clear that in the direction of some clusters one can expect to find a rich superposition of structures, sometimes at not too dissimilar redshifts. This could be due to the superposition, along the line of sight, of two or more clusters, clusters and groups, or even, several groups that mimic a cluster concentration. Thus, it is no surprise to find a number of examples (i.e., A295, A720, A919, A1505, A2128, and A2512) where it is difficult or impossible, with the present data, to ascertain a definitive cluster redshift, or even, in one or two examples (such as A720), to decide whether there is a cluster at all. How-
ever, the majority of this sample have Bautz-Morgan types I, III, and II, with one or two dominant galaxies. Thus, in general, we can expect that the derived redshifts will be the actual cluster redshifts in the large majority of cases.

A small number of discrepant velocities for some galaxies remained after the analysis, which could be due to misidentification at the telescope or to other causes. Particularly worrisome are such discrepancies in certain dumbbell components, which should be clarified by further observing.

## 7. SUMMARY

We give 130 new cluster redshifts, mostly for Abell clusters of Bautz-Morgan types I, I-II, and II. Therefore, most of the velocities reported are of galaxies of type $\mathrm{cD}, \mathrm{cD} / \mathrm{db}$, or outstanding ellipticals, leaving little room for membership and redshift uncertainties. We also confirm 32 values previously determined. However, two of them seem to be discordant with our values; most likely, they correspond to foreground galaxies superimposed on the clusters. For nine clusters, however, there are two possible redshifts. Only a larger sample of velocities can settle these ambiguities.

We would like to thank the directors of the Observatories of the Carnegie Institution of Washington and the Cerro Tololo Inter-American Observatory for the generous allocation of telescope time at Las Campanas and CTIO, and the staffs of these observatories for friendly support, in particular night assistants F. Peralta and A. Guerra at LCO. We thank A. Fairall and H. Rood for providing their catalogs in computer form, J. Melnick for discussions and help with the first Reticon observations, X. Cardenas for help in handling the Vidicon data, and C. Rios and G. Hertling for measuring some of the galaxy positions. This project was partially supported by FONDECYT grants 88-362, 90-371, and 193-0572 to H. Q.
